^{29}Si NMR, together with ^{27}Al NMR, has been used extensively to study structures of zeolitic molecular sieves. Klinowski (1993) has recently reviewed such applications.

3.3.3 Abundant Spin-$\frac{1}{2}$ Nuclei The combination of multiple-pulse homonuclear dipolar line narrowing with MAS to average out chemical-shift anisotropy is known as CRAMPS (combined rotation and multiple-pulse spectroscopy) and is the most effective approach for obtaining high-resolution ^{1}H spectra from organic solids. Figure 23 shows a comparison of spectra obtained by Dec *et al.* (1989) from a sample of powdered adipic acid, $HO_2CCH_2(CH_2)_2CH_2CO_2H$: (a) static, (b)–(d) MAS only at the indicated rates, (e) CRAMPS, and (f) CRAMPS on an expanded scale. Even with use of CRAMPS residual linewidths are still too great to facilitate widespread application of high-resolution ^{1}H NMR of solids because of the small proton chemical-shift range. Some applications to the study of hydrogen bonding and crystallographic nonequivalence have been reported.

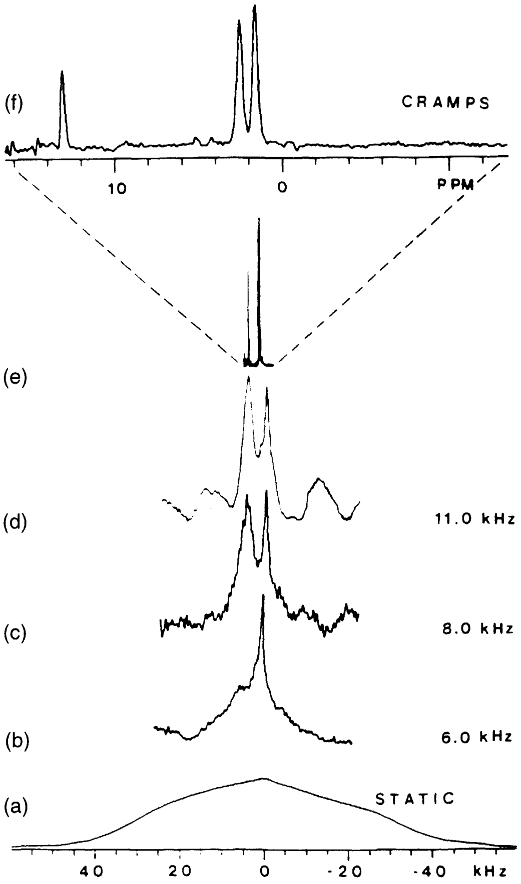

FIG. 23. ^{1}H NMR spectra of powdered, solid adipic acid, $HO_2CCH_2(CH_2)_2CH_2CO_2H$: (a) static sample, (b)–(d) MAS-only with indicated MAS speed, (e) CRAMPS, (f) CRAMPS, on an expanded scale. Reproduced with permission from Dec *et al.*, (1989).

3.3.4 Two-Dimensional Experiments with Spin-$\frac{1}{2}$ Nuclei Following the example of solution NMR, two-dimensional methodology (see Sec. 2.5) for solid-state NMR has begun to be developed in recent years. Such techniques are enabling the study of processes that include diffusion and exchange in solids as well as chemical-shift correlation and even resolution of *J* couplings in favorable cases. A few such experiments are mentioned briefly in this section. While still not in widespread use, $^{1}H/^{13}C$ 2D heteronuclear correlation experiments have been reported. In such experiments in the solid state, correlations are made through heteronuclear dipole interactions. Bronnimann *et al.* (1992) have applied the method to representative organic solids ranging from pure powdered crystalline compounds to lignite. Figure 24 shows the result obtained for monoethyl fumarate. For comparison, the 1D ^{1}H CRAMPS spectrum is displayed along the ^{1}H chemical-

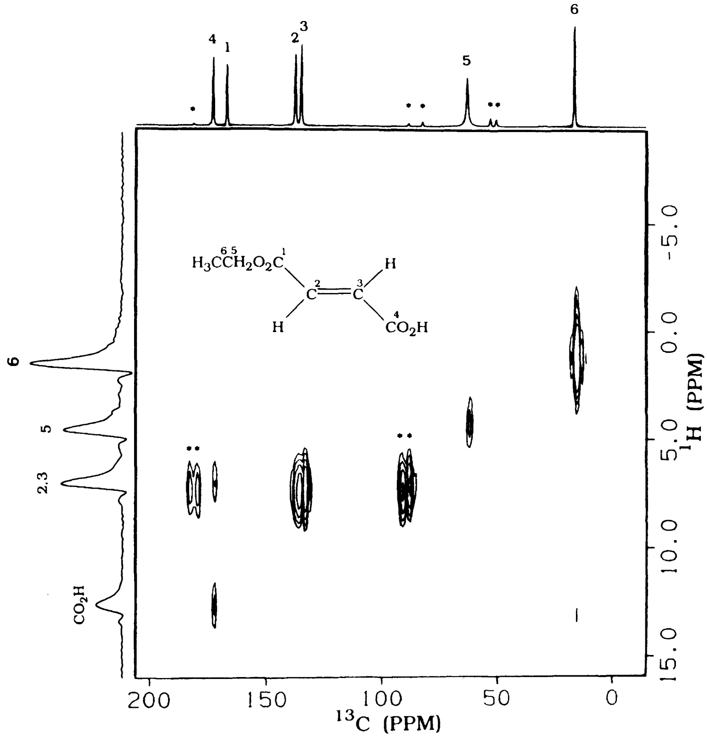

FIG. 24. The 2D HetCor contour spectrum, 1D ^{13}C CP/MAS spectrum (top), and 1D ^{1}H CRAMPS spectrum (left) of monoethylfumarate. Reproduced by permission from Bronniman *et al.*, (1992).

shift axis and the 1D ^{13}C CP/MAS spectrum along the ^{13}C chemical-shift axis.

A variety of methods has been used to achieve homonuclear correlations between dilute spin-$\frac{1}{2}$ nuclei, some through dipolar interactions and others through *J* couplings. Fyfe *et al.* (1992) have used the 2D ^{29}Si INADEQUATE experiment to obtain a complete Si–O–Si connectivity pattern for the zeolite ZSM-23.

While spin–spin coupling is rarely observed, even in high-resolution spectra, because it is usually so much smaller than other interactions, 2D *J*-resolved experiments can, in favorable cases, offer a means of significantly enhancing spectral resolution relative to 1D experiments. In a ^{31}P homonuclear experiment, Wu and Wasylischen (1992) have resolved $^2J_{PP}$ coupling constants in $RhCl(PPh)_3$.

High-resolution NMR is a valuable tool for studying exchange processes in solid samples in much the same way as it has been used in solution-state NMR for many years. 2D exchange spectroscopy (EXSY) is one of the NMR experiments used in such studies. Cross peaks link the signals of exchanging atoms, and exchange rates can also be obtained from spectra. Aliev and Harris (1993) have used 2D ^{13}C CP/EXSY to study conformational exchange properties of monosubstituted cyclohexanes, $C_6H_{11}X$, in thiourea inclusion complexes.

3.3.5 Quadrupolar Nuclei Line-narrowing techniques involving fast sample spinning can usefully be carried out on quadrupolar nuclei provided the magnitude of the quadrupolar interaction is not too large. In discussing techniques it is helpful to distinguish between quadrupolar nuclei with integral and half-integral spins. Half-integer spins have a central $m_I = \frac{1}{2}$ to $m_I = -\frac{1}{2}$ transition that is unaffected to first order by the quadrupolar interactions, whereas for integer spins all transitions are affected. In the latter case even fast MAS (~20 kHz) is of little value in significantly removing or reducing the quadrupolar contribution, except for ^{2}H where the interaction is relatively small or for a nucleus in a high-symmetry site. While several applications of MAS deuterium NMR to isotopically enriched samples have been described, reports on natural-abundance studies are now also beginning to appear, and Poupko *et al.* (1994) have reported the determination of deuterium interaction constants from such studies.

Most high-resolution studies of quadrupolar nuclei with nonintegral spins have been concerned with the observation of the central transition. While this is not affected by first-order quadrupolar interactions, there is a shift and broadening due to second-order effects. A description of the origins of these is beyond the scope of this article. The second-order interaction is inversely proportional to the static magnetic field, and resolution can be improved by working at higher magnetic fields. MAS will partially but not completely average the second-order effects, and Alemany (1993) has reviewed the factors involved in obtaining meaningful, fast MAS NMR spectra from such nuclei with particular emphasis on ^{27}Al ($I = \frac{5}{2}$) NMR of catalysts and minerals. In addition, Klinowski (1993) has described applications of the study of the same nucleus to obtain information about aluminum coordination sites in zeolitic and aluminophosphate molecular sieves. In some cases (see Ganapathy *et al.*, 1982), spinning at angles other than the magic angle gives better resolution, but in most cases lines remain broad in comparison with the results obtained for spin-$\frac{1}{2}$ nuclei.

In recent years Pines's group (see Chmelka *et al.*, 1989) have devised and applied two elegant experiments, double rotation (DOR) and dynamic-angle spinning (DAS), which average the anisotropic second-order, quadrupolar broadening and give spectra with much narrower signals than MAS. DOR involves the simultaneous rotation of the sample around two axes inclined at angles corresponding to zeros of the second and fourth Legendre polynomials, 54.74° (magic angle) and 30.6°. Experimentally, this is achieved with a large outer rotor spinning at the magic angle accommodating a smaller inner rotor containing the sample that spins at an angle of 30.6° with respect to the spinning axis of the outer rotor. Figure 25 shows a comparison of the ^{17}O NMR spectra obtained (a) by MAS, and by DOR with the outer rotor spinning at (b) 540 Hz and (c) 680 Hz, for an ^{17}O-enriched sample of diopside, $CaMgSi_2O_6$. Three isotropic center-band peaks, corresponding to different oxygen sites, are observed and labeled on the spectra.

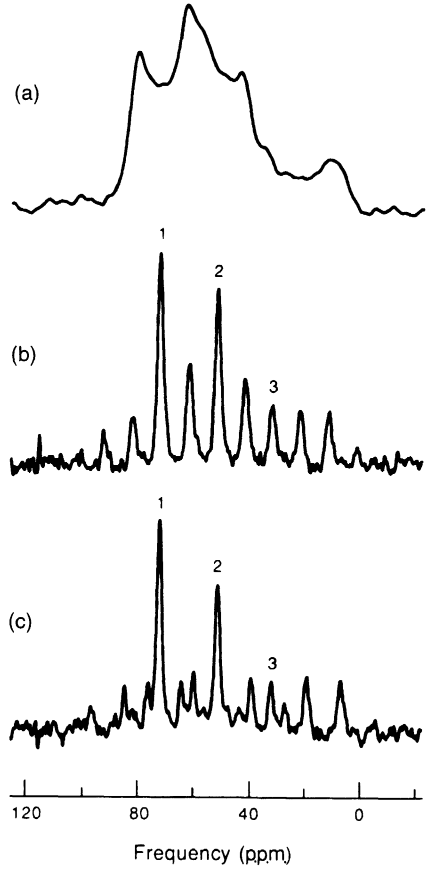

FIG. 25. ^{17}O NMR spectra of diopside, $CaMgSi_2O_6$: (a) MAS, (b), (c) DOR with outer rotor spinning at (b) 540 Hz and (c) 680 Hz. Reproduced with permission from Chmelka *et al.*, (1989).

In the DAS experiment second-order quadrupolar interactions are averaged by reorienting a sample about a time-dependent axis. Spin evolution occurs at two different angles of the sample rotor in order for the broadening from both the quadrupolar and chemical shift anisotropies to disappear. Baltisberger *et al.* (1992) have reported ^{87}Rb DAS NMR results for five inorganic rubidium salts. Narrow lines were obtained from each distinct rubidium site. The experiment was performed at four magnetic-field strengths for $RbNO_3$, which enabled the isotropic chemical shift and a product of the quadrupolar coupling constant and the quadrupolar asymmetry parameter to be calculated. A two-dimensional DAS experiment is also described in the same article that involved three orientations of the rotor relative to the magnetic field. In this experiment, the isotropic signals from the different rubidium sites in $RbNO_3$ were resolved in one dimension and the powder pattern cross sections in the other. Simulation of the latter for each site enabled the quadrupolar coupling constant and asymmetry parameter to be obtained for the various sites.

GLOSSARY

Chemical Shift: The displacement of an NMR signal relative to that of a reference material. Chemical shifts are expressed on a field-independent scale in ppm, by the displacement in hertz divided by the applied magnetic field in megahertz.

Cross Polarization: A process that enhances the magnetization of rare spins in a magnetically dilute spin system by transferring magnetization from abundant nuclei such as ^1H and hence increases the NMR signal.

Dipole–Dipole Coupling: Direct interaction between the magnetic moments of two nuclei.

Fourier Transformation: The mathematical operation that converts an FID time-dependent signal into the frequency domain.

Free-Induction Decay (FID): The decaying signal that is recorded as a function of time at the end of a pulse experiment.

Magic-Angle Spinning: Rotating a sample at an angle of 54° 44′ to the applied magnetic field.

Magnetogyric Ratio: The proportionality constant relating the magnetic moment of a nucleus to the spin I of the nucleus.

Nuclear Overhauser Enhancement (NOE): The change in the intensity of the NMR signal from a nucleus A caused by irradiation at the resonance frequency of a second nucleus B. NOEs can be either homonuclear or heteronuclear in origin.

Powder Pattern: An envelope of NMR responses from all possible orientations to the applied magnetic field of a spin system in a solid sample.

Quadrupole Interaction: For nuclei with spin $>\frac{1}{2}$, interaction between the nuclear electric quadrupole moment and the non-spherically-symmetrical field gradient around the nucleus.

Relaxation Time: The time taken by spins to relax to thermal equilibrium after radio-frequency excitation. The exponential decay of magnetization back along the x axis is characterized by the spin–lattice relaxation time T_1. The spin–spin relaxation time T_2 characterizes the process by which spins fan out in the xy plane.

Spin–Spin Coupling: Indirect coupling between nuclear spins transmitted by electrons and characterized by a coupling J.

INTRODUCTION

Ceramics are any of a class of inorganic, nonmetallic products that have been subjected to a high temperature during manufacture or use. Typical ceramics are metallic oxides, although borides, carbides, nitrides, silicides, covalent compounds of nonmetals (e.g., B, C, Si), and mixtures or composites of such materials are also ceramics.

The fundamental principle of materials science is that the properties of a material originate from its structure. The structure of a material may be considered on many dif-

ferent levels: microstructure, defect structure, atomic structure, electronic structure, and nuclear structure, each of which may influence the physical and chemical properties of the material.

At the most fundamental level, the atoms of the various elements differ in the amount of charge on their nuclei and the number of electrons they attract to neutralize this charge. The nature of the electron configuration that shields the nuclear charge dictates the type of chemical bonding (see CRYSTALLINE STATE) in which an atom may engage and directs such fundamental properties as thermal, optical, electrical, and magnetic behavior. The nature of the chemical bonding in turn determines the type of material that may form (metal, ceramic, or polymer).

Atoms and molecules arrange themselves in space in patterns that will minimize the electrostatic energy. These arrangements (crystal structure) may be periodic (crystals) or nonperiodic (amorphous or quasicrystalline materials). Disturbances of the strict periodicity of the crystal arise from the presence of various kinds of defects. Multiple-element materials may also exhibit marked deviations from stoichiometry. The defect structure can frequently play an important role in the properties of ceramics.

The microstructure of a material describes the way crystallites pack together and involves the grains, grain boundaries, size and shape of grains, grain orientation, and porosity. Microstructure also determines many properties, e.g., mechanical, electrical, optical, and magnetic properties. Most of the time, even when the property itself originates from the electronic, crystal, or defect structure, the property of the final ceramic material is more closely related to the control of microstructure. When more than two phases are present, the multiple-phase structure, which includes the type, size, distribution, connectivity, and amount of the phases, is also a part of the microstructure.

In this article, structures of ceramics are described in terms of crystal structure, defect structure, and microstructure. The relations of structures and properties are also discussed. For mechanical behavior, the brittle nature of the ceramics and the toughening mechanisms are mentioned. The role of structures in electrical and magnetic properties are discussed in some practically important ceramic systems.

1. BONDING

Bonding in ceramics spans the range from nearly completely ionic (LiF) to purely covalent (C). Metallic and van der Waals bonds may be present but rarely predominate. The tendency toward ionic bonding between atoms increases as the difference in the electronegativity of the constituent atoms increases. Materials comprising a single group-IV element such as carbon or silicon, with zero electronegativity difference, can thus be associated with pure covalent bonding. The fractions of ionic and covalent characters for simple ceramic compounds are given in Table 1.

2. CRYSTAL STRUCTURES

The ways in which individual atoms in ceramic compounds are arranged geometrically depends on several factors, including the type of bonding, the relative sizes of the atoms, and the need to balance electrostatic charges.

In covalent crystals, each atom is surrounded by a specific number of other elements arranged according to the bond directionality. In purely ionic crystals, the bond is not directional, and the relative atomic sizes and charge-balance factors become of increasing importance. In most oxides, the oxygen ions form close-packed arrays, and the metallic ions, which are usually smaller, are arranged in the interstices (Fig. 1). Thus the larger the relative difference in the radius of

Table 1. Fractions of ionic and covalent bondings for simple compounds (Davidge, 1979).

Compound	Electronegativity difference	Fraction ionic bonding	Fraction covalent bonding
LiF	3.0	0.89	0.11
MgO	2.3	0.73	0.27
Al_2O_3	2.0	0.63	0.37

Si_3N_4	1.2	0.30	0.70
SiC	0.7	0.11	0.89
Si	0	0.00	1.00

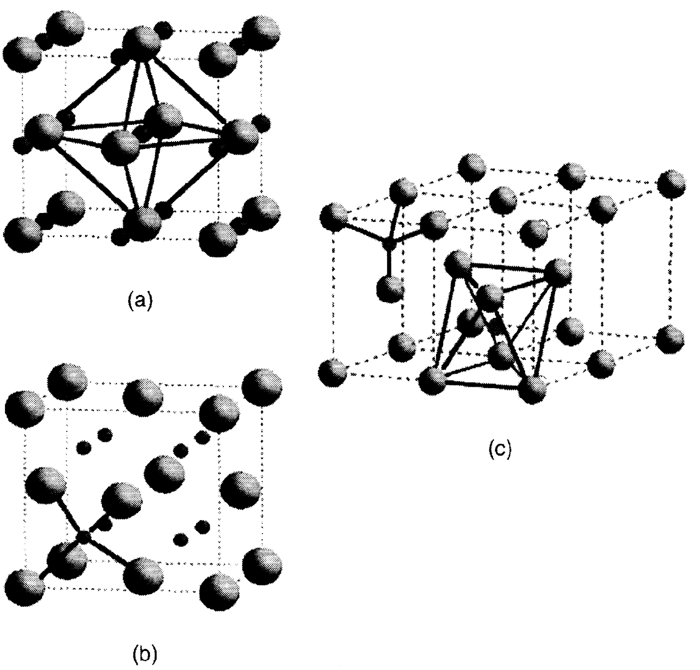

FIG. 1. (a), (c) Octahedral and (b), (c) tetrahedral interstices in (a), (b) cubic close-packed and (c) hexagonal close-packed lattice. Large spheres are anions.

the ions, the smaller the expected coordination number. A wide range of ceramic structures can be classified in terms of anion packing, the pattern of cation sites, or coordination polyhedra and their linkage. They will be categorized according to cation–anion (A:X or B:X) ratios and will be grouped as AX, AX_2, A_2X, A_2X_3, ABX_3, etc. (Table 2). The names of structure types are usually (but not always) taken from the simplest representative of the family. Some are taken from the first member of the family that was carefully

Table 2. Summary of ceramic crystal structures (after ASM Handbook, 1991; Megaw, 1973).

Name	Anion packing	Sites by cations[a]	CNs[b]
Rock salt	Cubic close-packed	All oct.	6:6 AX

---

[a] Tet.: tetrahedral sites; oct.: octahedral sites.
[b] CNs: coordination numbers ("6:3 AX_2" means the CNs of A and X are 6 and 3, respectively).

studied. For more detailed information about the space groups provided for each structure type, see CRYSTALLOGRAPHY.

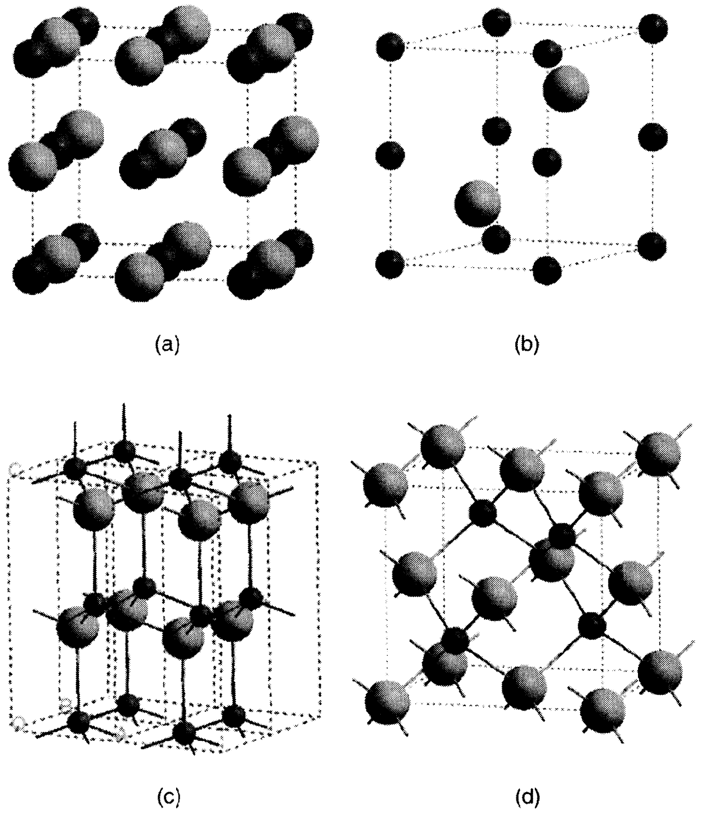
2.1 AX

2.1.1 Rock-Salt Structure (*Fm*3*m*) This structure consists of a cubic close-packed anion lattice in which all octahedral interstitial sites are filled with cations [Fig. 2(a)]. Both anions and cations are octahedrally coordinated. Ionically bonded binary compounds with radius ratios between 0.73 and 0.41 favor octahedral coordination and crystallize in this structure. Compounds exhibiting this structure include most alkali halides (except CsCl, CsBr, and CsI); oxides, sulfides, selenides, and tellurides of Mg, Ca, Sr, Ba, etc.

2.1.2 Nickel Arsenide Structure ($P6_3/mmc$) Binary compounds with radius ratios between 0.73 and 0.41 possessing some degree of covalent bonding adopt the nickel arsenide structure. This structure consists of a hexagonal close-packed lattice of anions with cations filling all octahedral interstices [Fig. 2(b)]. Cations are octahedrally coordinated, and each anion is surrounded by six cations at the corners of a trigonal prism. Compounds exhibiting this structure include NiAs, FeS, NiS, VS, CoS, FeSe, CoSe, etc.

2.1.3 Wurtzite Structure ($P6_3mc$) Binary compounds with radius ratios between 0.22 and 0.41 and a strong covalent contribution to bonding favor tetrahedral coordination for both constituents. These requirements can be met with hexagonal packing of the large oxygen ions with half the tetrahedral interstices filled with cations [Fig. 2(c)]. Compounds exhibiting this structure include ZnS, CdS, ZnO, BeO, SiC, AlN, GaN, InN, etc.

2.1.4 Zinc Blende Structure (*F*43*m*) Binary compounds with radius ratios between 0.22 and 0.41 and a strong covalent contribution to bonding can also be stable in



(a) (b) (c) (d)

FIG. 2. (a) Rock-salt, (b) nickel arsenide, (c) wurtzite, and (d) zinc blende structures.

the zinc blende structure. This structure [Fig. 2(d)] is similar to the diamond structure, except that each atom is tetrahedrally coordinated by the other element. Cations fill half the tetrahedral interstices of the cubic close-packed anions. Compounds exhibiting this structure include ZnS, BeS, CdS, GaAs, BeO, SiC, InSb, etc.

2.1.5 Cesium Chloride Structure (*Pm*3*m*) For binary compounds with radius ratios greater than 0.73, stability requires that the atom should be eight-fold coordinated, which is accomplished in a simple cubic lattice of one element with the large interstice at the body-centered position filled with the other element [Fig. 3(a)]. Compounds exhibiting this structure include chlorides, bromides, and iodides of Cs and Tl.

2.2 *AX*$_2$

2.2.1 Fluorite Structure (*Fm*3*m*) For compounds with radius ratios greater than 0.73, eightfold coordination is favored. This is realized in the fluorite structure, which consists of a simple cubic anion lattice with half of the body-centered positions filled with cations [Fig. 3(b)]. This structure is the same as CsCl with the exception that only half of the cation sites are occupied. Compounds exhibiting this structure include ZrO_2, HfO_2, CeO_2, ThO_2, UO_2, PrO_2, CaF_2, SrF_2, BaF_2, ZrF_2, HfF_2, HgF_2, SrF_2, CdF_2, PbF_2, BaF_2, $BaCl_2$, etc.

2.2.2 Rutile Structure (*P*4$_2$/*mnm*) *AX*$_2$ compounds with radius ratios between 0.41 and 0.73 can have the rutile structure, in which cations are octahedrally coordinated by anions, and each anion is bonded to three cations (Fig. 4). Cations fill half the available octahedral sites, and the closer packing of oxygen ions around the filled cation sites leads to the distortion of the nearly close-packed anion lattice. Compounds exhibiting this structure include TiO_2 (rutile), SnO_2, MnO_2, GeO_2, PbO_2, VO_2, NbO_2, WO_2, CrO_2, MoO_2, CoO_2, RuO_2, IrO_2, OsO_2, MgF_2, ZnF_2, MnF_2, FeF_2, NiF_2, $CaBr_2$, etc.

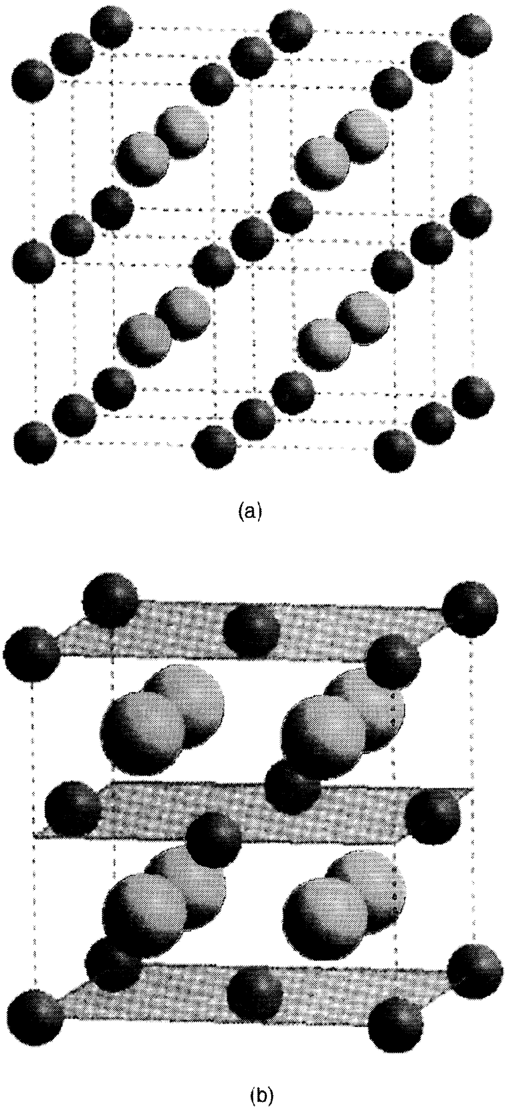


FIG. 3. (a) Cesium chloride structure (eight unit cells) and (b) fluorite structure (one unit cell). All the body-centered positions are occupied in cesium chloride, while in fluorite only half are occupied.

2.2.3 Cadmium Iodide Structure (*P*$\bar{3}$*m*1) This structure is a layer structure consisting of planes of cations sandwiched between planes of anions. The sandwich is the repeat unit in the *z* direction. Each cation is surrounded by six anions forming an octahedron. Each anion also has six neighbors, three cations on one side of it and three anions on the other. Anions form a hexagonally packed array. The octahedral sites between pairs of anion planes are occupied by cations. Compounds exhibiting this structure include CdI_2, MgI_2, CaI_2, PbI_2, $MgBr_2$, $FeBr_2$, $Mg(OH)_2$, $Ca(OH)_2$, etc.

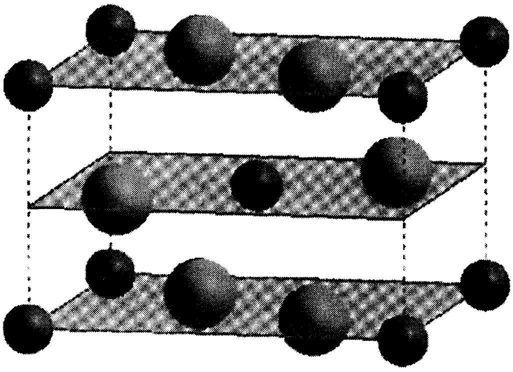

FIG. 4. A unit cell of rutile structure.

2.2.4 Cadmium Chloride Structure ($R\bar{3}m$)

This is also a layer structure like the CdI_2 structure. The layers are the same in both structures, but they pack differently. The cation environment is the same as in the CdI_2 structure. However, the anion still has three cation neighbors on one side and three anions on the other, the six taken together constituting a trigonal prism. Compounds exhibiting this structure include $CdCl_2$, $MgCl_2$, $FeCl_2$, ZnI_2, etc.

2.2.5 Structures of Silica

Crystalline silica (SiO_2) exists in several different polymorphic forms corresponding to different ways of combining corner-sharing SiO_4 tetrahedra. There are three basic structures: quartz, tridymite, and cristobalite, all of which exist in high- and low-temperature modifications.

The ideal cristobalite structure ($Fd3m$) can be described in terms of the zinc blende lattice. The A atoms occupy both the A and X sites of the zinc blende structure with one X atom midway between each pair of A atoms [Fig. 5(a)]. Each A atom is surrounded by four X atoms that form a tetrahedron. Each X atom is coordinated by two A atoms.

The ideal tridymite structure ($P6_3/mmc$) is related to wurtzite in the same way that cristobalite is to zinc blende. If all A and X positions in wurtzite are replaced by A atoms, and X atoms are introduced midway between the A atoms, it is the structure of tridymite. The A atoms are again tetrahedrally coordinated, while the X atoms are surrounded by two A atoms.

In quartz ($P6_222$ or $P3_221$), the atoms are coordinated in the same manner, and the silica tetrahedra are arranged in a hexagonal

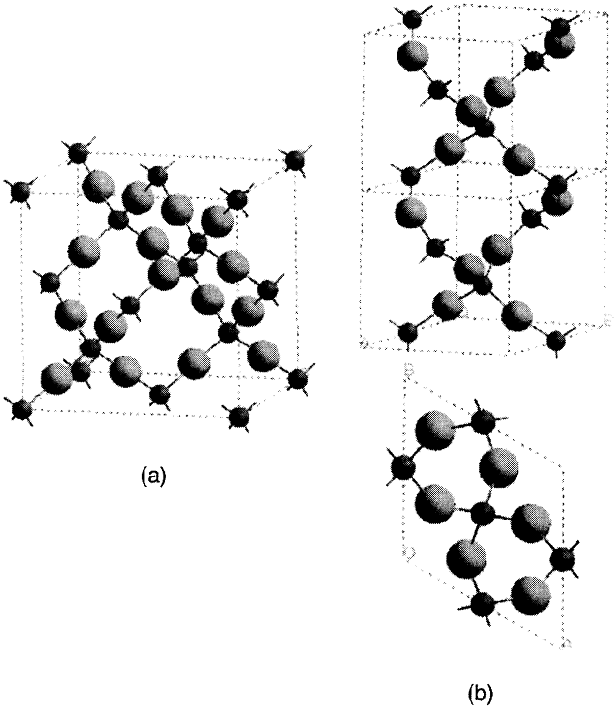

FIG. 5. The structures of (a) cristobalite and (b) quartz. Both are high-temperature forms. A projection on the xy plane of quartz is also included.

array [Fig. 5(b)]. For more detailed information on silica, see SILICON DIOXIDE; QUARTZ.

2.3 A_2X

2.3.1 Antifluorite Structure (*Fm*3*m*) This structure consists of a cubic close-packed lattice of anions with cations arranged in the tetrahedral sites. This structure has cation and anion positions exactly reversed from the normal fluorite lattice. Compounds exhibiting this structure include Li_2O, Na_2O, K_2O, Rb_2O, and various sulfides.

2.4 A_2X_3

2.4.1 Corundum Structure ($R\bar{3}c$) This structure consists of a nearly hexagonal close-packed anion lattice with cations filling two-thirds of the octahedral sites [Fig. 6(a)]. The cations are in approximate octahedral coordination. When cations fill adjacent octahedra, they repel each other so that neither is exactly centered on its site. The anion positions are also slightly distorted. Compounds exhibiting the corundum structure include α-Al_2O_3 (corundum), Cr_2O_3, Fe_2O_3, V_2O_3, Ti_2O_3, Rh_2O_3, Ga_2O_3, etc.

2.5 AB_2X_4

2.5.1 Spinel Structure (*Fd*3*m*) The spinel structure consists of a cubic close-packed anion lattice with divalent metal cations occupying one-eighth of the tetrahedral sites and trivalent metal cations occupying one-half of the octahedral sites (Fig. 7). The cubic unit cell is large, comprising eight formula units and containing 64 tetrahedral (*A*) and 32 octahedral (*B*) sites; eight of the *A* sites and 16 of the *B* sites are occupied. Compounds exhibiting the spinel structure include $MgAl_2O_4$ (spinel), $FeAl_2O_4$, $ZnAl_2O_4$, $MnFe_2O_4$, $ZnFe_2O_4$, $CdFe_2O_4$, $TiMg_2O_4$, $MoNa_2O_4$, $NiLi_2F_4$, $CuTi_2S_4$, Mn_3O_4, Co_3O_4, etc.

2.5.2 Inverse Spinel Structure The divalent ions switch sites with half of the trivalent ions in the normal spinel structure. As a consequence, the A^{2+} ions and half the B^{3+} ions are on the octahedral (*B*) sites, while the other half of the B^{3+} are on tetrahedral (*A*) sites [B(AB)O_4]. Compounds exhibiting inverse spinel structure include $FeMgFeO_4$, $FeNiFeO_4$, $FeCoFeO_4$, $FeCuFeO_4$, $FeTiFeO_4$, $InFeInO_4$, $MgTiMgO_4$, $ZnSnZnO_4$, $ZnTiZnO_4$, $CoSnCoO_4$, $GaMgGaO_4$, $InMgInO_4$, $InCoInO_4$, $InNiInO_4$, Fe_3O_4, etc.

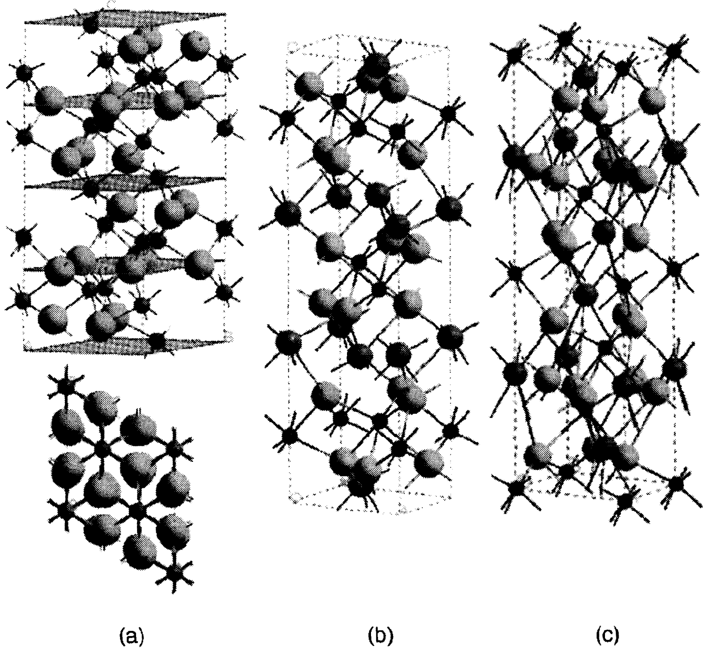

FIG. 6. (a) Corundum, (b) ilmenite, and (c) lithium-niobate structure.

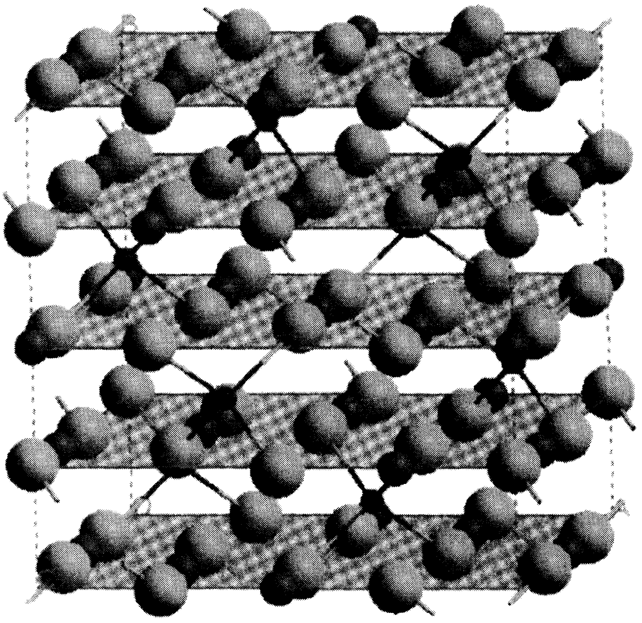

FIG. 7. Spinel structure. The four-fold coordination of the cations in *A* sites are indicated with lines.

2.6 ABX_3

2.6.1 Perovskite Structure (*Pm*3*m*) This structure consists of a cubic close-packed anion lattice in which one-fourth of the anions are replaced by a large cation (*A*), and a smaller highly charged cation (*B*) occupies one-fourth of the octahedral interstices (Plate 1). Alternatively, it can be described as a simple cubic unit cell with a large cation on the corners, a smaller cation in the body center, and oxygens in the centers of the faces. The structure is a network of corner-linked oxygen octahedra, with the smaller cations filling the octahedral holes and the large cation filling the dodecahedral holes.

The stability of this structure depends critically on the relative sizes of the cations. Most compounds with this structure form distorted perovskite cells in which the atoms are slightly displaced from the ideal positions. The flexibility of the perovskite structure allows a wide range of solid solutions. It is possible to substitute an element of a different valence, in which case the resulting charge imbalance is usually accommodated by the formation of oxygen vacancies. Some of the compounds can accommodate a large number of point defects and still remain stable. Perovskites and spinels typify many ceramic materials in which electrical or magnetic properties are important.

Compounds exhibiting perovskite structure include $CaTiO_3$ (perovskite), $BaTiO_3$, $SrTiO_3$, $PbTiO_3$, $CdTiO_3$, $SrSnO_3$, $CaSnO_3$, $BaSnO_3$, $CaZrO_3$, $SrZrO_3$, $PbZrO_3$, $BaZrO_3$, $CdCeO_3$, $CaCeO_3$, $SrCeO_3$, $PbCeO_3$, $BaCeO_3$, $SrHfO_3$, $BaHfO_3$, $BaPrO_3$, $BaThO_3$, $KNbO_3$, $NaNbO_3$, $LaAlO_3$, $YAlO_3$, $LaMnO_3$, $LaFeO_3$, $LaCrO_3$, $PbMgF_3$, $KZnF_3$, $KNiF_3$, $NaWO_3$, $KMgF_3$, $PbMg_{1/3}Nb_{2/3}O_3$, etc., and the structures of most of the cuprate superconductors are based on the perovskite structure.

2.6.2 Ilmenite Structure (*R*$\bar{3}$) ABX_3 compounds in which the relative sizes of the cations do not allow the perovskite structure to be stable adopt the ilmenite structure. This structure is similar to the corundum structure except that the two cations reside in the octahedral sites in alternating layers [Fig. 6(b)]. Compounds exhibiting ilmenite structure include $NiTiO_3$, $MnTiO_3$, $NiMnO_3$, $CoMnO_3$, $MgTiO_3$, $CoTiO_3$, $FeTiO_3$, $CdTiO_3$, etc.

2.6.3 Lithium Niobate Structure (*R*3*c*) This structure is the same as the ilmenite structure except that each layer of cations contain an ordered arrangement of two cations [Fig. 6(c)]. Compounds exhibiting this structure include $LiNbO_3$, $LiTaO_3$, etc.

2.7 A_2BX_4

2.7.1 Olivine Structure (*Pbnm*) The olivine structure is based on a hexagonal close packing of anions in which half of the octahedral sites and one-eighth of the tetrahedral sites are occupied by *A* and *B* cations, respectively. Compounds exhibiting this structure include $(Mg,Fe)_2SiO_4$ (olivine), Mg_2SiO_4, Fe_2SiO_4 (fayalite), γ-Ca_2SiO_4, Mg_2GeO_4, Al_2BeO_4, Na_2BeF_4, $CaMgSiO_4$, $LiMnPO_4$.

2.8 Others

2.8.1 Graphite (*P6₃/mmc*) The sp^2 hybridized bonding in graphite results in a hexagonal layered structure with strong σ bonds between carbon atoms in the plane and weaker interaction between π bonds between the planes [Fig. 8(a)]. Compounds/elements exhibiting this structure include carbon and BN.

2.8.2 Diamond (*Fd3m*) When carbon bonds consist of hybrid sp^3 orbitals, the atoms must be tetrahedrally coordinated [Fig. 8(b)]. This structure is essentially the same as the zinc blende structure except that only one element is present.

2.8.3 High-Temperature Superconductors In $YBa_2Cu_3O_7$ (*Pmmm*), the Cu atoms occupy two sites on both sides of the Ba–O planes. On one side, CuO_2 sheets sandwich the Y atoms with the Cu atoms having a square pyramidal (fivefold) coordination. The Cu–O atoms on the other side of the Ba–O planes form linear chains with Cu atoms having fourfold planar coordination, which leads to an orthorhombic lattice. The structures can be derived from three perovskite unit cells ($ACuO_3$) by stacking them with the cation sequence of -Y-Ba-Ba-Y-Ba-Ba- on the *A* site and removing two (out of nine) oxygens per unit cell. In fact, all of the high-T_c cuprate superconductors have structures related to perovskite (Park and Snyder, 1995).

3. DEFECT STRUCTURES

Disturbances of the strict periodicity of the crystal arise because of defects. These are characterized by dimensions as point defects (vacancies, interstitial atoms, substitutional atoms), one-dimensional (dislocations), two-dimensional (low- and high-angle grain boundaries, stacking faults, external surfaces), or three-dimensional defects (inclusions, pores). In addition to structural defects, crystals also contain electronic imperfections (i.e., electrons and holes), which either can be formed intrinsically through ionization of electrons or may be formed in association with point defects.

Numerous oxides exhibit marked deviations from stoichiometry. Some oxides are even known to be unstable when stoichiometric. Wustite, e.g., which is nominally written as FeO, has under all equilibrium conditions a deficiency of iron ($Fe_{1-y}O$). An exact stoichiometric composition in ceramic compounds is in principle the exception rather than the rule (Kofstad, 1972). For

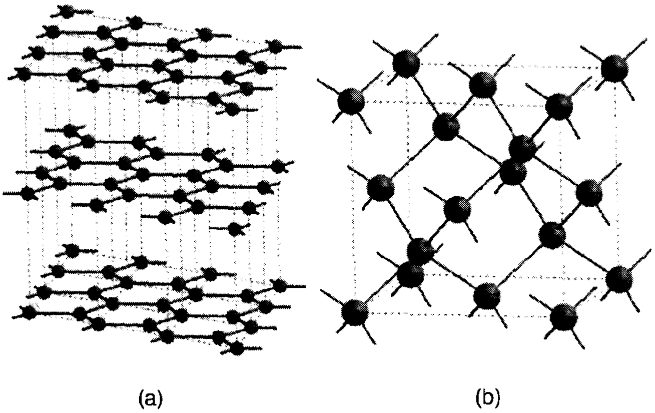

FIG. 8. Structures of (a) graphite and (b) diamond.

more detailed information, see POINT AND OTHER DEFECTS IN CRYSTALS.

3.1 Defect Structures in Stoichiometric Oxides

If a charged point defect is formed in a stoichiometric crystal with composition MO, a complementary point defect with opposite effective charge must be formed to maintain the electrical neutrality of the stoichiometric crystal. In general, the types of defect found in a binary ionic crystal are Schottky ($V_M + V_O$), Frenkel ($V_M + M_i$), and anion-Frenkel ($V_O + O_i$) disorder.

3.2 Defect Structures in Nonstoichiometric Oxides

Nonstoichiometry in a compound is equivalent to the presence of point defects, and the extent of nonstoichiometry is a direct measure of the net concentration of the corresponding defect(s) in a compound. While complementary point defects are formed in stoichiometric crystals, the electrical neutrality of nonstoichiometric compounds is conserved through formation of point defects and complementary electronic defects.

3.2.1 Oxygen-Deficient Oxides When a nonstoichiometric oxide is oxygen deficient, the predominating defects may be oxygen vacancies (V_O), interstitial metal ions (M_i), or both. If oxygen vacancies predominate, the formula of an oxide, say MO_2, may be written as MO_{2-x} [Fig. 9(a)]. If interstitial cations predominate, the composition can be written as $M_{1+y}O_2$ [Fig. 9(b)]. If both types are present, the formula may be written as $M_{1+y}O_{2-x}$. The formation of oxygen vacancies or interstitial cations leads to the formation of complementary free electrons, and electrical conductivity by transport of electrons can result (n-type conductor). Examples of oxides exhibiting overall oxygen deficiency are TiO_2, ZrO_2, CeO_2, Nb_2O_5, etc.

3.2.2 Metal-Deficient Oxides When a nonstoichiometric oxide is metal deficient, the predominating defects may be metal vacancies (V_M), interstitial oxygen atoms (O_i), or both. The formation of charged metal-ion vacancies results in complementary positive electronic defects (holes). In such oxides the electrical conductivity involves the transport of holes (p-type conductor).

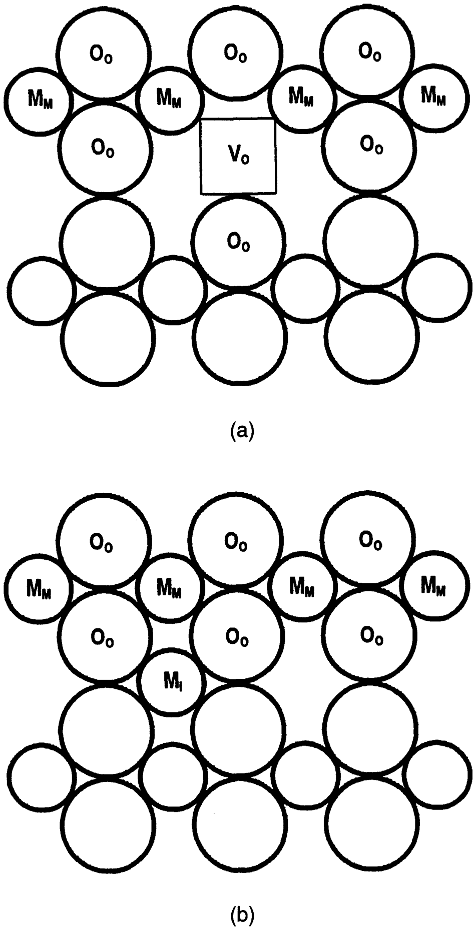

FIG. 9. Oxygen-deficient oxides. (a) MO_{2-x} in which oxygen vacancies (V_O) predominate, and (b) $M_{1+y}O_2$ in which interstitial cations (M_i) predominate.

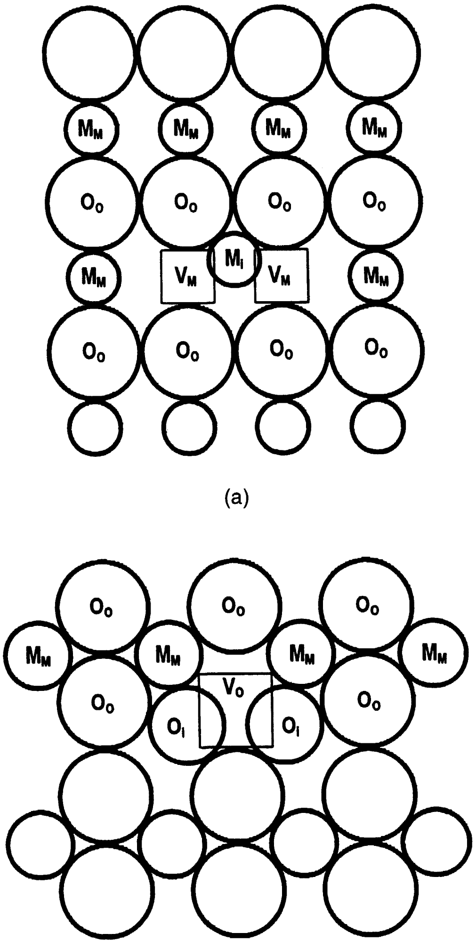
In metal-deficient oxides where the disorder is limited to the cation lattice, the point defects can be associated and form complex combinations. In the case of $Fe_{1-y}O$ (rock-salt structure), for each Fe ion vacancy created as a result of nonstoichiometry, an equal number of Frenkel defect pairs are simultaneously formed in the metal lattice resulting in the formation of complex defects ($V_{Fe}Fe_iV_{Fe}$) [Fig. 10(a)]. Well-known examples of oxides with cation vacancy-type defects are MnO, FeO, CoO, NiO, Cu_2O, etc.

If the disorder in a metal-deficient oxide is limited to the oxygen lattice, the point de-



(a)

(b)

FIG. 10. Metal-deficient oxides. (a) $M_{1-y}O$ with complex metal vacancy defect, and (b) a complex oxygen interstitial defect in an oxide M_{2+x} with excess oxygen.

fects may constitute single interstitial oxygen atoms or ions in a manner illustrated in Fig. 9(b) for interstitial cations. But, as in the case of the metal-vacancy defects, interstitial oxygen can form complex interstitial-oxygen defects. In the case of UO_{2+x}, vacant oxygen sites are also created as a result of the introduction of the interstitial oxygen ions. The creation of these defects can be visualized by assuming that each excess interstitial oxygen ion displaces one of the neighboring oxygen ions into a neighboring interstitial position [Fig. 10(b)].

4. MICROSTRUCTURE

Generally, a polycrystalline ceramic material is a complex system composed of crystallites, grain boundaries, and pores. In addition, secondary phases and inhomogeneity in compositions may be present, particularly at grain boundaries. Such microstructural parameters greatly affect the performance of the material even when the property itself originates from the structural parameters on an atomic level. The type of atomic bonding and crystalline structure that determine whether a material is brittle, semiconducting, magnetic, etc. may be masked or enhanced by the microstructure.

The fundamental microstructural parameter in polycrystalline ceramic materials is the grain boundary. The study of the effect of grain size and shape, grain orientation, grain-boundary chemistry, and porosity is of considerable importance to understanding the material properties.

Porosity is almost always present as a phase in ceramics. This results primarily from the relatively high solubility of gases at high temperatures and the slow rate of sintering, especially when the initial material is coarse grained. Pores can be open to the surface and connected to one another (open porosity) or isolated from the surface (closed porosity).

Grain boundaries have a particularly profound effect on the microstructure-sensitive properties of ceramics such as mechanical behavior. In pure single-phase materials, grain boundaries are simply the surfaces separating the individual crystallites, and they can be regarded as thin regions of atomic disarray where the atomic density is slightly lower than normal. Grain boundaries can thus act as sources of and sinks for structural defects such as point defects and dislocations and as sites for pores. In impure materials, the impurities and second phases are almost always localized at grain boundaries, which can lead to a variety of phenomena.

Grain-boundary–pore interactions—whether pores move when attached to the grain boundaries or grain boundaries break away from the pores—largely determine the degree of densification because grain boundaries provide an easy route for diffusion of pores during sintering. Therefore, grain growth in ceramics is seldom determined by the intrinsic grain-boundary mobility but is usually controlled by the presence of impurities and pores. The specific problems encountered in studies of grain-growth phenomena in ceramics include the dominant role of impurities, the effects resulting from a charged grain boundary, and the effects of solute segregation and phase separation near grain boundaries.

The crystallographic orientation of the individual grains may not be randomly distributed but can exhibit a preferred orientation. This effect can be critical when there is anisotropy in properties.

Chemical homogeneity is another factor to be considered when correlating microstructure and property. Chemical inhomogeneity can result in a nonuniform microstructure and thus make interpretation of the effects of other microstructural parameters ambiguous.

The parameters affecting the microstructure are usually correlated so that optimization of a particular property is a complex process. The various microstructural parameters can be controlled by processing conditions and also by changing the starting composition of the material. Many additives are used to adjust the microstructure for desired properties. The concentration and distribution of the additives (and/or impurities) also affect the evolution of the microstructure.

A typical and very well-known example of a microstructural control in ceramics is MgO-doped Al_2O_3, where MgO acts as a grain-growth inhibitor and can lead to a fine-grained, pore-free, microstructure. The detailed mechanisms of how MgO acts to change the microstructure evolution in Al_2O_3 are still not fully understood (Bennison and Harmer, 1990). The amount of MgO required is a few hundred ppm and is sometimes even lower in concentration than the amount of background impurities. Al_2O_3 responds to MgO doping in different degrees, depending on its synthesis and the background impurity level (MgO has been observed to increase densification directly in some powders and to decrease densification directly in others). The single most important effect of MgO doping is its ability to reduce significantly the grain-boundary mobility, regardless of the presence of varying background impurities, through a solid-solution pinning mechanism. The pinning action of MgO reduces the tendency for pore–grain-boundary separation and abnormal grain growth arising from inhomogeneous densification and nonuniform liquid phase distribution.

Various properties will respond to the microstructure differently. The magnetic permeability, e.g., has a definite linear relationship with the mean grain size (if the pores remain at the grain boundary). On the other hand, the critical flaw size is roughly equal to the largest microstructural feature, i.e., not the mean grain size, but the largest grain size in the structure (when the grain size is the dominant parameter). Thus small mean grain size is not sufficient to give high strength. A narrow grain-size distribution together with small mean grain size is required for high mechanical strength. This is a typical example of the influence of the microstructure on a "bulk" property (permeability) and a "critical" property (mechanical strength) (Stuijts, 1977).

5. STRUCTURES AND MECHANICAL BEHAVIOR

5.1 Brittleness

The most distinguishing mechanical property of ceramics is their brittleness—that is, catastrophic failure following an almost entirely elastic deformation. Strong covalent/ionic bonding, which is dominant in the crystal lattice of ceramic materials, leads to a high melting point, high corrosion resistance, high wear resistance against abrasion, high hardness, high Young's modulus, etc. On the other hand the strong covalent/ionic bonding hinders the movement of adjacent atoms/ions so that the motion of a dislocation is either absent or present to a very limited extent except at very high temperatures.

A much smaller number of independent slip systems is available in ceramics than in metals. The slip systems for a number of common ceramic crystals are summarized in Table 3. In ionic crystals, a dislocation must also maintain the cation–anion site ratio, which makes the dislocation motion even more difficult. The Burgers vector in ceramics is greater than that found in metals, which means that more energy is required to initiate the dislocation motion in ceramics.

Table 3. Primary slip systems of ceramics at low temperature. At high temperature, slip can occur on other planes. Those for fcc metal systems are included for comparison. (After Davidge, 1979; Kingery *et al.*, 1975.)

Material	Crystal structure	Primary slip system	NSS[a]
Al_2O_3	Hexagonal	$0001\langle 11\bar{2}0\rangle$	2
BeO	Hexagonal	$0001\langle 11\bar{2}0\rangle$	2
MgO	Cubic (NaCl)	$110\langle 1\bar{1}0\rangle$	2
$MgAl_2O_4$	Cubic (spinel)	$111\langle 1\bar{1}0\rangle$	5
β-SiC	Cubic (ZnS)	$111\langle 1\bar{1}0\rangle$	5
β-Si_3N_4	Hexagonal	$10\bar{1}0\langle 0001\rangle$	2
TiC	Cubic (NaCl)	$111\langle 1\bar{1}0\rangle$	5
UO_2	Cubic (CaF_2)	$001\langle 1\bar{1}0\rangle$	3
Cu, Ag, etc.	fcc metals	$111\langle 110\rangle$	12

[a] Number of associated independent slip systems.

The fewer slip systems, problems associated with charge neutrality, and longer Burgers vector add up to a much greater resistance to plastic deformation in crystalline ceramics than in their metallic counterparts.

The high toughness of metals, in comparison to ceramics, is a result of plastic deformation, which occurs by movement of dislocations. The plasticity found in metals is not possible in ceramics, resulting in the brittleness of ceramics.

On loading, the ceramic will deform elastically until it fractures catastrophically. This behavior can be understood in terms of the stress that is concentrated at the crack-tip region. The level of these stress concentrations can be described by introducing a stress intensity factor (K): $\sigma \sim K\alpha^{-1/2}$, where σ and α are applied stress and crack length, respectively. A crack can proceed when K becomes higher than a critical value (critical stress intensity factor or fracture toughness, K_{IC}): $\sigma_f \sim K_{IC}\alpha^{-1/2}$ where σ_f is the fracture strength. Improvement of fracture strength basically can be achieved by either a smaller starting crack length (by modifying the process) or a higher value of K_{IC} (by toughening) (Schubert and Petzow, 1988). For more detailed information on mechanical properties, see the related articles in this encyclopedia (MECHANICAL PROPERTIES OF SOLIDS; CERAMICS, MATERIAL PROPERTIES OF)

The strengthening of metals can be accomplished by controlling the movement of dislocations. In ceramics that have high shear strength combined with crack sensitivity and low fracture strength, toughening can be obtained by controlling the propagation of cracks. Just as in metals, high toughness and high strength do not generally co-exist. Toughening mechanisms in ceramics can lower the strength. The strength, however, is no more sensitive to damage or handling because the toughened ceramics become more crack resistant and can retain strength better.

5.2 Toughening Mechanisms

5.2.1 Transformation Toughening

The transformation-toughening concept exploits the martensitic transformation of ZrO_2 [Fig. 11(a)]. The stable form of ZrO_2 at room temperature has monoclinic symmetry with seven-fold coordination of the cation. The following transformations take place at elevated temperatures: monoclinic–1200°C–tetragonal–2300°C–cubic–2600°C–melt. Partially stabilized zirconia (PSZ) is a two-phase material that consists of precipitates of tetragonal and/or monoclinic phase (depending on the heat treatment) dispersed in a cubic matrix. CaO,

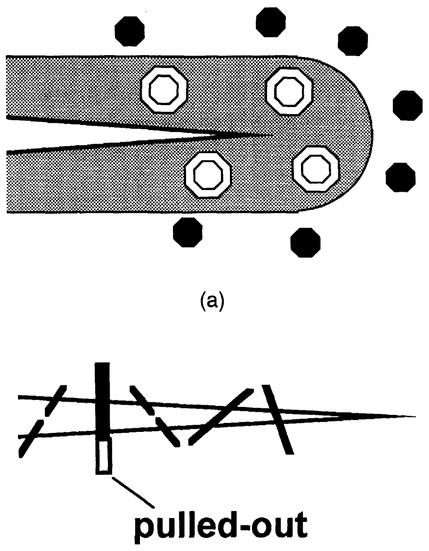


FIG. 11. (a) Stress-induced transformation toughening. Black particles are original metastable tetragonal ZrO_2 particles. The white ones are martensitically transformed monoclinic particles. (b) Fiber reinforcement toughening.

MgO, or Y_2O_3 is commonly used as stabilizing agent.

The tetragonal-to-monoclinic phase transformation (t-m transformation) at ~1200 °C is accompanied by a volume increase of 3–5%. Both shear and tension promote the transformation, while compression hinders it. On cooling from high temperature, the t-m transformation takes place accompanied by a volume change. If the grains are embedded in a stiff matrix (cubic ZrO_2 or another ceramic such as Al_2O_3), the volume increase would create compressive stress and therefore hinder the transformation. In practice, the t-m transformation temperature can be depressed by several hundred degrees Celsius. In the systems that are used in practical applications such as Mg–PSZ, Al_2O_3–ZrO_2, and Y–TZP (tetragonal zirconia polycrystal), the tetragonal phase can be retained down to temperatures even below room temperature.

When shear or tensile stresses are applied, however, the transformation is triggered. In the stress field ahead of a crack tip, shear and tensile stresses are always present and are usually strong enough to start the t-m transformation. There is a critical stress required to transform the tetragonal grains. The zone in which the transformation occurs has a shape similar to the plastic zone in metals. The tetragonal ZrO_2 grains in this zone undergo transformation with a volume increase. The resulting compressive stress acts on the crack tip, reducing the stress concentration, and, thus, quenches the fracture.

5.2.2 Microcracking Another toughening mechanism is induced by the dispersion of unstabilized ZrO_2 particles in a matrix. Upon cooling, the unstabilized particles transform to the monoclinic phase, and the resultant stress field (due to the volume expansion) causes localized microcracking around the ZrO_2 particles. These microcracks can absorb or dissipate the energy of a propagating crack by extending in its stress field or by deflecting it, thereby increasing the toughness of the ceramic. The toughness will increase to a maximum, above which microcracks generated by the ZrO_2 particles will interact with each other resulting in a decrease in strength.

In addition to the phase transformation, residual stress can be caused by the thermal expansion mismatches (in multiple-phase systems), thermal expansion anisotropy, or elastic anisotropy. These residual stresses can also contribute to the toughening by forming microcracks.

5.2.3 Whisker or Fiber Reinforcement Whiskers or fibers densely embedded within a matrix (see COMPOSITE MATERIALS) may have thermal expansion coefficients or Young's modulus values different from those of the matrix material [Fig. 11(b)]. Consequently, on cooling from the sintering temperature, the different shrinkages of the matrix and the inclusions lead to residual stress. For inclusions with lower expansion coefficients, the inclusion is under compression and induces radial compressive stress and tangential tensile stress in the matrix. This residual stress field is superposed on the applied stress and results in crack deflection. The crack is deflected onto the inclusions, creating a zig-zag-shaped crack path. If the amplitude of this deflection path is large enough, additional frictional forces will appear over the crack surfaces. This changes the stress concentrations around the crack tip and reduces the driving force for crack propagation.

In addition to the above effect, a pullout mechanism is possible if the whiskers/fibers are oriented orthogonally to the crack plane and to the direction of crack propagation and if the interfaces between the inclusions and the matrix are weak. On loading, the matrix material will fracture, but the stronger inclusion will stay intact. At a critical stress, the inclusions are pulled out of their original position. This movement requires the friction at the interface to be overcome, and the frictional forces "bridge" the crack surfaces, which changes the stress concentrations ahead of the crack tip. The pullout effect also leads to crack-energy dissipation and, hence, material toughening.

5.2.4 Ductile Dispersion Toughening The incorporation of a ductile metal phase can also improve the toughness (e.g., Al_2O_3/Al, WC/Co, etc.). The brittle matrix preserves stiffness and lightness, and the metal phase enhances toughness and energy absorption capacity. However, the properties of the two phases must be such that the propagating crack is attracted to the ductile phase.

6. STRUCTURES OF ELECTROCERAMICS

6.1 $BaTiO_3$

$BaTiO_3$ exhibits a perovskite structure. Both Ba^{2+} and O^{2-} ions have similar ionic radii and together form a face-centered cubic array. Octahedrally coordinated Ti^{4+} ions located at the center of the cubic perovskite cell are the polarizable active ions promoting ferroelectricity and the high permittivity of $BaTiO_3$. On cooling from high temperature, the crystal structure of $BaTiO_3$ undergoes phase transformation from paraelectric cubic to ferroelectric tetragonal at ~130 K (Curie point, T_c).

The interesting electrical properties of this material arise from the Ti–O plane. The octahedral site for Ti is large compared to the size of the Ti ion. The rattling titanium model suggests the presence of minimum-energy positions for the Ti ion that are off center (Fig. 12). The off-centered Ti ions give rise to the electric dipole. At temperatures higher than T_c, the thermal energy is such that the Ti ion has no fixed unsymmetrical position, leaving the structure with an average cubic symmetry. However, even at high temperatures, the open octahedral site allows the Ti ion to develop a large dipole moment in an applied field.

The most interesting properties of $BaTiO_3$ are found at or around T_c. In the tetragonal phase, the linear expansion coefficient along the *c* axis is negative, which means that the crystal structure becomes less and less tetragonal as temperature increases toward the transition temperature. The material is much less polarizable (thus low permittivity) along the *c* axis than in the perpendicular directions. In the vicinity of T_c, the stability of the lattice decreases, and the amplitude of the displacement of the Ti^{4+} ions inside the oxygen octahedral becomes very large. This induces a strong variation of the polarizability and, consequently, a large increase in the permittivity.

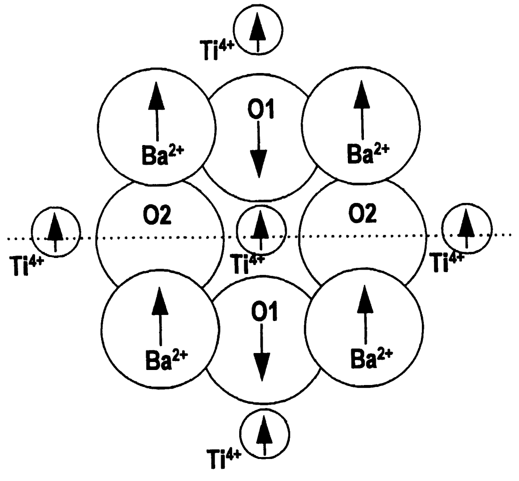

FIG. 12. Ion displacements in the cubic–tetragonal distortion in $BaTiO_3$.

Additions or substitutions of cations can shift the T_c, introduce second phases, restrict domain-wall motion, control crystallite size, or change the defect structure. Shifting the T_c enables the peak permittivity to be put in a temperature range in which it can be exploited. The substitution of Sr^{2+} for Ba^{2+} or of Sn^{4+} or Zr^{4+} for Ti^{4+} lowers T_c, while the substitution of Pb^{2+} for Ba^{2+} increases it. Cations that have a higher valency than those they replace (e.g., La^{3+} in place of Ba^{2+} or Nb^{5+} in place of Ti^{4+}) generally enhance grain growth when dopant level is small but inhibit grain growth when concentration of the dopant gets high. Figure 13 shows the $BaTiO_3$ grains of different sizes obtained in a thin trilaminate. The middle layer with small grains is undoped, and the left and right layers with larger grains are doped with La^{3+} and Mn^{3+}.

$BaTiO_3$, when doped with ions of higher valence such as La^{3+}, Ce^{3+} (for Ba^{2+}), or

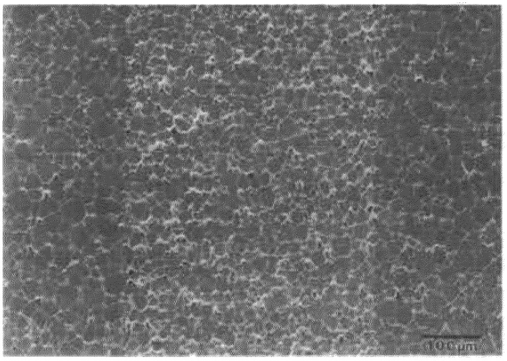

FIG. 13. SEM micrograph of a thin $BaTiO_3$ trilaminate. The large grains in left/right layers were obtained by adding La^{3+} and Mn^{3+} (Capurso, *et al.*, 1995).

Nb^{5+} (for Ti^{4+}), also exhibits interesting semiconducting properties. A large increase in electrical resistance (PTCR effect: positive temperature coefficient of resistivity) occurs over a limited temperature range near the T_c. This semiconducting property of $BaTiO_3$ is connected with grain-boundary resistivity effects in combination with the ferroelectric–paraelectric phase transition.

When sintered at high temperature, La-doped $BaTiO_3$ becomes an *n*-type semiconductor with conduction taking place via transfer of electrons between Ti ions (Ti^{4+} and Ti^{3+}). Thus the $BaTiO_3$ grains are conducting and remain conducting on cooling to room temperature. But the grain-boundary region changes during cooling. Oxygen is adsorbed on the surface of the ceramic and diffuses along grain boundaries. The added oxygen ions assist cation vacancies to form at the grain boundary and to diffuse slowly into the grains. They form a thin layer at the grain boundaries in which they compensate the donors, thereby creating an insulating barrier between grains. The net result of this process is that the ceramic consists of semiconducting grains separated by thin insulating grain boundaries. The electrical resistance of the ceramic is inversely proportional to grain size because smaller grains mean more insulating grain boundaries and, therefore, higher resistance.

Below T_c, the resistivity is low because the electron charge trapped in the grain-boundary region is partially compensated by spontaneous polarization. Wherever the domain structure is favorably positioned, a positive polarization charge will cancel the negatively charged barriers between conductive grains, thereby establishing low-resistivity paths across the ceramic.

Above T_c, the spontaneous polarization disappears, and the resistivity increases, giving rise to the PTCR effect. At first the increase is slow because of the high permittivity at T_c. The barrier height is inversely proportional to the permittivity of the surrounding medium. A highly polarizable medium shields the charges trapped at the grain boundary, reducing the barrier height and the electrical resistance. As the temperature increases further above T_c, the permittivity decreases rapidly according to the Curie–Weiss law. Decreases in permittivity cause rapid increase in the barrier between grains and an increase in the electrical resistance. Eventually the resistance increase levels off as the decrease in permittivity slows down and the normal NTC (negative temperature coefficient) effect takes over. High density, very fine-grained material is desirable for high dielectric constant, while porosity and fine grain size is required for high PTCR effect (Moulson and Herbert, 1990; Newnham, 1983, 1984).

6.2 ZnO Varistor

ZnO varistors (voltage-dependent resistors) are ZnO-based ceramic semiconductor devices with highly nonlinear current (*I*)-voltage (*V*) characteristics. The electrical behavior depends both on the type and amount of oxide additives and on the ceramic microstructure. The microstructure can be visualized as shown in Fig. 14. The resistance is controlled by the region in which the ceramic grains contact one another in much the same way as in the semiconducting $BaTiO_3$ showing PTCR effect.

The basic building block of the varistor is the ZnO grains. During sintering, various cations are distributed in such a way that the near–grain-boundary region becomes highly resistive (~10^{12} Ω cm), and the grain interior becomes highly conductive (~10 Ω cm). A sharp drop in resistivity from the grain boundary to grain occurs within a distance of ~100 nm. This area is known as the depletion layer. Thus, at each grain boundary, there exists a depletion layer on both

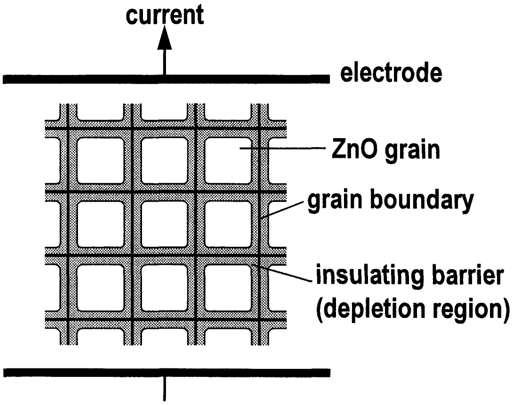

FIG. 14. Schematic of the microstructure of ZnO varistor.

sides of the grain boundary extending into the adjacent grains. The varistor action arises as a result of the presence of this depletion layer within the grains. This depletion layer provides a barrier to the transport of electrons across the grain boundary.

The theoretical and experimental studies of this barrier conform to a classical Schottky-barrier model, with positive charges residing in the depletion layer and the compensating negative charges at the grain-boundary interface as traps. Since the region near the grain boundary is depleted of electrons, a voltage drop appears across the grain boundary upon application of an external voltage. This macroscopic breakdown voltage per intergranular barrier (barrier voltage) is typically of the order of ~2–4 V/barrier.

The electrical characteristics of the ZnO varistors are therefore related to the bulk structure; i.e., the device is inherently multijunction with varistor action shared between the various ZnO grain boundaries. This implies that tailoring the device breakdown voltage is simply a matter of fabricating a varistor with the appropriate number of grains in series between the electrodes. Thus to achieve a given breakdown voltage, one can change the varistor thickness (for fixed grain size) or alternatively one can vary the grain size (for fixed thickness) to change the number of barriers.

Many oxides (Bi, Co, Cr, Mn, Sb, Al, Nb, Ba, Ni, etc.) can be added to ZnO either to impart or to improve or adjust the nonlinear *I-V* characteristics. These oxide additions can affect the varistor properties both directly and indirectly: directly by segregating at the grain boundaries and changing the *I-V* characteristics, indirectly by affecting the microstructural development. Because the varistor breakdown voltage is inversely proportional to the average grain size of the ZnO, it is important to understand the effects of the individual oxide additions on the microstructure of ZnO varistors. For example, Sb_2O_3 and Al_2O_3 react with ZnO and form the $Zn_7Sb_2O_{12}$ spinel-type and $ZnAl_2O_4$ spinel structures, respectively. These spinel particles are insulating and play only a secondary role in determining device properties, but they reduce the rate of ZnO grain growth (Levinson and Philipp, 1986; Newnham, 1984).

7. STRUCTURES OF FERRITES

7.1 Spinel Ferrites

An important family of ferrites are spinels with the chemical formula MFe_2O_4, in which M represents a divalent ion such as Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, or a combination of ions with an average valence of 2.

The cation distribution can be disordered, particularly at high temperatures, and all the ferrimagnetic spinels are more or less inverse. The site preference of the metallic ions determines the saturation magnetization of the material and can be explained by the ionic radius and the size of the lattice site. The divalent ions are generally larger than the trivalent, and the *B* sites are larger than *A*. Therefore, it would be reasonable that the trivalent ions and the divalent ions would go into the *A* and *B* sites, respectively. Two exceptions are found in Zn^{2+} and Cd^{2+}, which prefer *A* sites because of their electronic configurations.

The exchange force between the moments of two metal ions on different sites depends on the distances between them, the oxygen ion that links them, and also the angle between the three ions. The interaction between moments on *A* and *B* sites is greatest. The *BB* and *AA* interactions are much weaker.

In case of Zn ferrite ($ZnFe_2O_4$), the *A* sites are occupied by Zn^{2+} ions, which, being nonmagnetic (having no unpaired electronic spins), do no ordering of the ions on the *B* sites occupied by Fe^{3+} ions. The interactions between Fe^{3+} ions (*BB* interaction) are negligible. In Ni ferrite ($NiFe_2O_4$), the Fe^{3+} ions fill the eight *A* sites while the other eight Fe^{2+} ions and eight Ni^{2+} ions go on the *B* sites. The antiferromagnetic interaction orients the eight Fe^{2+} moments and eight Ni^{2+} moments antiparallel to the eight Fe^{3+} moments on the *A* sites. The Fe^{3+} ion moments will cancel, but the moments on the Ni^{2+} ions give rise to an uncompensated moment or magnetization.

In mixed Zn–Ni ferrite where Zn replaces some (e.g., half) of the Ni, four Zn^{2+} and four Fe^{3+} ions fill the eight *A* sites and twelve Fe^{3+} and four Ni^{2+} ions go on the *B* sites. The Fe^{3+} moments in the *A* sites neutralize only one-third of those in *B* sites, leaving the other two-thirds oriented but uncompensated, giving a net magnetic moment. The total uncompensated oriented ions consist of one-half of the Fe^{3+} ions plus all the Ni^{2+} ions, giving a large magnetic moment (Buchanan, 1986; Kingery *et al.*, 1975; Moulson and Herbert, 1990). For more detailed information, see MAGNETIC MATERIALS; MAGNETIC ORDERING IN SOLIDS.

7.2 Magnetoplumbite

The magnetoplumbite structure is hexagonal, and therefore it shows strong uniaxial anisotropy along the *c* axis, which is the preferred axis (often called the easy direction) for magnetization to be oriented. The general formula is $M\text{Fe}_{12}\text{O}_{19}$ (or $M\text{O}\cdot 6\text{Fe}_2\text{O}_3$ giving rise to the common name "hexaferrites"), where *M* can be Ba, Sr, or Pb. A unit cell contains two formula units, i.e., a total of 64 ions. The M^{2+} and O^{2-} ions together form a close-packed structure with some of the layers cubic close packed and others hexagonal close packed. Of the twelve Fe^{3+} ions in a formula unit, nine are on octahedral sites, two on tetrahedral sites, and one on a five-coordinated site. Seven of the ions on octahedral sites and the one on a five-coordinated site have their spins in one direction, and the remainder are oppositely directed. Thus there are four more ions with spins in the one sense than there are with opposing spins. Since there are five electrons with parallel spins in each Fe^{3+} ion, there are 20 unpaired spins per formula unit. The presence of a unique axis in hexagonal ferrites, which cannot be found in spinel structures, contributes to the high coercivities that make these materials useful as hard ferrites (Buchanan, 1986; Moulson and Herbert, 1990).

7.3 Microstructures of Ferrites

Some factors such as saturation magnetic moment are a function only of a chemical composition and crystal structure. Others, such as permeability and losses, are strongly dependent on microstructural conditions.

Both the grain size, porosity, and the distribution of porosity determine the initial permeability. Grain boundaries and other defects such as pores, second phases, cracks, and impurities can impede domain-wall motion and decrease the permeability. Therefore, the permeability increases with increasing grain size and decreasing porosity. In practice the permeability increases with increasing average grain size up to a certain point and drastically decreases with increasing percentage of grains possessing pores (intrangranular pores) despite increasing grain size.

Exaggerated grain growth can also trap pores within grains during growth, and hence pin domain walls and finally lower permeability and increase losses. This would happen by inhomogeneous distribution or segregation of impurities or dopants such as SiO_2 and CaO, which produce rapid grain growth locally.

When grain size is very small, the grains cannot support domain walls. Therefore, only the rotational motion of domains contribute to permeability. Larger grains contain domain walls, and their movement is only limited by the grain boundaries and the defects included inside the grain (such as intragranular pores). Therefore, motion of domain walls is sensitive to grain size and the distribution of pores. If pores are suppressed or located at the grain boundaries, the permeability will increase with grain size.

Hysteresis loss is controlled by the same factors that control the low-frequency permeability and coercivity (grain size, porosity, impurities, etc.). The lowest hysteresis losses are achieved with minimum anisotropy, large and uniform grain sizes associated with reduced grain-boundary areas, and low intergranular porosity.

The eddy-current losses that are important for high-frequency operation can be reduced by increasing the resistivity. Resistivity can be increased by adding CaO and SiO_2. Ca and Si ions substitute in the ferrite crystal lattice close to the grain boundary, rendering the grain-boundary region insulating. Resistivity can also be increased by sintering in oxidizing atmospheres, which induces preferential grain-boundary oxidation by lowering Fe^{2+} concentrations (this suppresses electron hopping between Fe^{2+} and Fe^{3+}). Eddy-current losses can be further reduced by reducing grain size and increasing porosity, which increases the total volume of the resistive region.

Therefore, there is a compromise between the large-grain, dense ferrites for high permeability at low frequencies and the small-grain, porous ferrites for low losses at high frequencies (Buchanan, 1986; Moulson and Herbert, 1990).

GLOSSARY

Burgers Vector: Displacement vector necessary to close a stepwise loop around a dislocation.

Coercive Force: The magnetizing force that must be applied in the direction opposite to that of the previous magnetizing force in order to reduce magnetic flux density to zero.

Coordination Number: The number of anions surrounding each metal ion.

Covalent Bond: A primary bond in which two atoms share a pair of electrons.

Curie Temperature: The temperature marking the transition between ferromagnetism and paramagnetism, or between the ferroelectric phase and paraelectric phase.

Defect Structure: A complete description of the point and electronic defects in a compound and their concentrations as a function of temperature and partial pressure of the constituent atoms or molecules.

Domain: A part of a crystal in which all of the magnetic moments are cooperatively aligned.

Electronegativity: A qualitative property that is a measure of the power of an atom in a molecule to attract electrons to itself.

Fracture Toughness: The ability to carry loads or deform plastically in the presence of a notch.

Ionic Bond: A primary bond arising from the electrostatic attraction between two oppositely charged ions; a type of chemical bonding in which one or more electrons are transferred completely from one atom to another, thus converting neutral atoms into electrically charged ions.

Partially Stabilized Zirconias: Two-phase materials that consist of precipitates of tetragonal and/or monoclinic phase (depending on the heat treatment) dispersed in a cubic matrix. CaO, MgO, or Y_2O_3 are commonly used as stabilizing agent.

Permeability: A generic term used to express various dynamic relations between magnetic induction (B) and magnetizing force (H), under various conditions of magnetic excitation.

Remanent Magnetization: The magnetic induction remaining in a magnetic material after removal of the applied magnetizing force.

Slip System: A combination of families of crystallographic planes and directions corresponding to dislocation motion.

Stoichiometric: Having the precise weight relation of the elements in a chemical compound; or (quantities of reacting elements or compounds) being in the same weight relation as the theoretical combining weight of the elements involved.

INTRODUCTION

The number of potential applications for superconductors in electrical circuits, both lumped and continuous, is large. Some applications merely require replacing an Ohmic material with a superconductor to reduce system loss and improve sensitivity. Microwave circuits made with superconducting striplines are one such example. However, like the laser, superconductivity is a quantum phenomenon that is accessible on a macroscopic scale. This unusual property allows engineers to build, for instance, magnetometers of great sensitivity by exploiting quantum interference. This article surveys both the passive devices used in microwave applications and the active devices used in applications as diverse as magnetometry, high-speed computation, and heterodyne mixing. In addition to the electrical engineering concerns, some of the materials issues associated with device fabrication are addressed.

1. BASIC PHYSICS OF SUPERCONDUCTORS

When a superconductor is cooled to a sufficiently low temperature, the motions of all its electrons will correlate into a *single* quantum state. All superconducting devices, in one way or another, take advantage of this property. According to the well-tested theory of John Bardeen, Leon Cooper, and Robert Schrieffer (BCS theory) (see Superconductivity, Low-Temperature), this correlation takes place when two electrons couple to form a Cooper pair. We may therefore think of the electrical charge carriers in a superconductor to be Cooper pairs (or more colloquially, superelectrons) with a mass m^* and a charge q^* that are twice those of normal electrons. The average distance between the two electrons forming a Cooper pair is known as the coherence length ξ_s. Both the coherence length and the binding energy of two electrons in a pair, 2Δ, depend on the particular superconducting material.

In a clean superconductor, where ξ_s is

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

much smaller than the carrier mean free path l, the BCS theory gives the coherence length as

$$\xi_{sc} = \hbar v_{\mathrm{F}} / \pi \Delta. \tag{1}$$

Here, $\hbar$ is the reduced Planck's constant, $h/2\pi$, and v_{F} is the Fermi velocity in the material. Equation (1) can be intuitively understood from the uncertainty principle in which the product of the position and momentum uncertainties of a Cooper pair must exceed $\hbar$. The position uncertainty is ξ_s, while the momentum uncertainty is approximately $\delta E / v_{\mathrm{F}}$, where δE is the uncertainty of the energy about the Fermi surface. Since $\delta E \approx \Delta$, Eq. (1) follows immediately. In a dirty superconductor, where ξ_{sc} is much larger than l, the usual random-walk argument (in three dimensions) leads to the dirty-limit coherence-length expression

$$\xi_{sd} = \sqrt{\xi_{sc} l / 3}. \tag{2}$$

It is inaccurate to think of Cooper pairs as tightly bound electron molecules. Instead, there are usually many other electrons between those of a specific Cooper pair, allowing for the paired electrons to change partners on a time scale of $h/2\Delta$. High-temperature superconductors form a significant exception to this observation, since their coherence lengths are typically on the order of the crystalline lattice spacing.

The pair correlation, and hence superconductivity, can be destroyed by providing energy to the Cooper pairs in excess of their binding energy. This energy can be thermal, and so superconductivity exists only below a critical temperature T_c. Other types of depairing energy are kinetic, resulting in a critical current density J_c, and magnetic, resulting in a critical field H_c.

2. GENERAL ELECTROMAGNETIC PROPERTIES OF SUPERCONDUCTORS

The two hallmark electromagnetic properties of all superconductors are the ability to support a static current without any electrical resistance and the ability to *exclude* a static magnetic flux from the interior of the material. Although the first property is the better known, it is the second property, known as the Meissner effect, that distinguishes a superconductor from a perfect conductor (which only *conserves* a static magnetic flux in its interior).

An extremely useful, yet simple, model for superconductivity can be developed through a set of constitutive relations that describe these two hallmark properties. The zero dc resistance criterion implies that the superelectrons move unimpeded in a superconductor. Therefore, by assuming that the charge carriers do not scatter incoherently, the standard Ohmic conduction model extended to superconductivity becomes

$$\frac{\partial}{\partial t} (\mu_0 \lambda^2 \mathbf{J}_s) = \mathbf{E}, \tag{3}$$

where $\mathbf{J}_s$ is the supercurrent density, $\mathbf{E}$ is the electric field, μ_0 is the permeability of the material, and λ is the penetration depth, defined as $\lambda \equiv \sqrt{m^* / n^* (q^*)^2 \mu_0}$. Here, n^* is the density of the supercurrent carriers. Equation (3) is known as the first London equation after its originators, Heinz and Fritz London. This expression reveals that the superelectrons' inertia creates a lag between their motion and that of an applied electric field. As a result, a superconductor will support a time-varying voltage drop. The impedance associated with the supercurrent is therefore inductive, and it will be useful to think of $\mu_0 \lambda^2$ as a kinetic inductance created by the correlated motion of the Cooper pairs.

Substituting the first London equation into Faraday's law and integrating with respect to time yields the second London equation,

$$\nabla \times (\mu_0 \lambda^2 \mathbf{J}_s) = -\mathbf{B}, \tag{4}$$

where $\mathbf{B}$ is the magnetic flux density and the integration constant has been set equal to zero. This latter choice is necessary so that the second London equation is consistent with the Meissner effect. This can be demonstrated by combining Eq. (4) with Maxwell's equations to obtain the vector Helmholtz equation:

$$\nabla^2 \mathbf{B} - \frac{1}{\lambda^2} \mathbf{B} = 0. \tag{5}$$

Physically, this result means that a superconductor will screen out an applied flux on a length scale of λ. Equation (5) reveals that the penetration depth λ plays a role in a superconductor analogous to that of the skin depth δ in an Ohmic conductor. The crucial difference is that the penetration depth does not depend on frequency.

The penetration depth is a function of temperature because the Cooper pairs can be destroyed thermally. Fitting to experimental data on conventional (low-T_c) superconductors results in the phenomenological expression

$$\lambda(T) = \frac{\lambda_0}{\sqrt{1 - (T/T_c)^4}} \quad \text{for } T \leq T_c, \tag{6}$$

where λ_0 is the penetration depth at zero temperature. Since broken Cooper pairs become normal electrons, Eq. (6) reveals how the conductance of a superconductor should behave:

$$\tilde{\sigma}(T) = \sigma_c (T/T_c)^4 \quad \text{for } T \leq T_c, \tag{7}$$

where σ_c is the dc conductance of the material at the critical temperature. Thus we find that transport in the superconductor occurs from two interpenetrating fluids created by the normal and superelectrons. Since the normal and supercurrent channels of transport are parallel, the effective conductance of a superconductor in the sinusoidal steady state is

$$\sigma = \tilde{\sigma} + \frac{1}{j\omega\mu_0\lambda^2}, \tag{8}$$

where the explicit temperature-dependent notation has been suppressed. The real part of σ is a result of the Ohmic loss in the normal transport channel, and the imaginary portion of σ is a result of the kinetic inductance in the supercurrent transport channel.

It should be noted that the temperature dependences given in Eqs. (6) and (7) are not precisely correct for the high-T_c materials. It has been suggested that this is because the angular momentum of the Cooper pairs in high-T_c materials is different than that in low-T_c ones. Nevertheless, the two-fluid picture of transport and its associated constitutive law, Eq. (8), are still valid for high-T_c superconductors.

Equation (8) is the central constitutive relation for the general electromagnetic properties of a superconductor. Although the model is relatively simple, it contains the essential features for making many engineering decisions. For example, typical electromagnetic calculations can be performed in the usual manner by simply including an additional energy storage term accounting for the lossless kinetic motion of the superelectrons. Table 1 shows the inductance L_0 and resistance R_0 per unit length of a single superconducting plate. Here the skin depth is calculated from the conductance $\tilde{\sigma}$: $\delta \equiv \sqrt{2/\omega\mu_0\tilde{\sigma}}$. For contrast, Table 2 shows the same quantities for an Ohmic plate. Both tables show quantities intrinsically associated with the plates only; inductance arising from geometrical considerations is not included.

3. PASSIVE SUPERCONDUCTING DEVICES

In many applications, the advantage of using a superconductor is a direct result of its low-loss properties. This is most obvious

Table 1. Summary of relevant lumped-element parameters per unit length associated with a single superconducting waveguide plate of thickness b and width d. It is assumed that the current is traveling along the length of the plate.

Case	Inductance/length L_0	Resistance/length R_0
$\lambda \ll \delta$, b arbitrary	$\frac{\mu_0\lambda}{d}\coth\frac{b}{\lambda}$	$\frac{1}{d\delta\tilde{\sigma}_0}\left(\frac{\lambda}{\delta}\right)^3 \frac{\sinh(2b/\lambda) + (\delta/\lambda)^2 \sin(2b\lambda/\delta^2)}{\sinh^2(b/\lambda)}$
$\lambda \ll \delta$, $\lambda \gg b$	$\frac{\mu_0\lambda^2}{db}$	$\frac{4}{db\tilde{\sigma}_0}\left(\frac{\lambda}{\delta}\right)^4$
$\lambda \ll \delta$, $\lambda \ll b$	$\frac{\mu_0\lambda}{d}$	$\frac{2}{d\delta\tilde{\sigma}_0}\left(\frac{\lambda}{\delta}\right)^3$

Table 2. Summary of relevant lumped-element parameters per unit length associated with a single Ohmic waveguide plate of thickness b and width d. It is assumed that the current is traveling along the length of the plate.

Case	Inductance/length L_0	Resistance/length R_0
$\delta \gg b$	$\mu b/3d$	$1/db\sigma_0$
$\delta \ll b$	$\mu\delta/2d$	$1/d\delta\sigma_0$

in microstrip circuits, where the microwave devices are patterned thin films. Such devices are termed "passive" since the films merely guide the electromagnetic energy in the circuit. Of all the superconducting materials that have been successfully grown in film form, Nb is the most common low-T_c material found in applications, while $YBa_2Cu_3O_7$ is the most common high-T_c material. Relevant material properties of these superconductors are found in Table 3. Some care is required when making estimates on anisotropic materials like $YBa_2Cu_3O_7$. Since $YBa_2Cu_3O_7$ is typically grown with its CuO planes parallel to the substrate (c axis perpendicular to the substrate), electrical transport occurs in the a-b planes. Consequently, although the magnetic fields inside a superconducting microstrip device are spatially decaying along the c direction, the appropriate value of λ is that for the a-b plane, the direction of electrical transport.

To gain the full advantage of a superconducting film in a microcircuit device, the supercurrent channel must dominate the normal channel. In other words, it is primarily the superelectrons, rather than the normal electrons, that screen electromagnetic fields from the material: $\lambda \ll \delta$. Inspecting Tables 1 and 2 shows that when this criterion is satisfied, the resistance per unit length for a superconducting plate drops from that of an Ohmic plate by an impressive factor of $(\lambda/\delta)^4$ in the thin-plate limit and $(\lambda/\delta)^3$ in the thick-plate limit. Experiments confirm this. At 1 GHz, the surface resistance of Nb at 7.7 K and $YBa_2Cu_3O_7$ at 77 K is about 2×10^{-6} Ω, over two orders of magnitude lower than that of Cu at 77 K. Of course, at higher frequencies the surface resistance of the superconductors is larger since it scales as ω^2, as seen in Table 1. At 10 GHz, for example, the measured surface resistance of $YBa_2Cu_3O_7$ at 77 K is roughly 200×10^{-6} Ω, but this value is still quite small. In fact, even at frequencies of 100 GHz, the surface resistance of $YBa_2Cu_3O_7$ at 77 K is smaller than that of cooled Cu.

3.1 Microwave Filters

The loss of surface resistance immediately translates into device performance improvement. For example, the insertion loss of a superconducting microwave device is much lower than that of a similar device made from Ohmic materials. Filters with sharper bandpass skirts are possible using superconducting materials. This is because the number of poles in the transfer function of a microcircuit filter is directly related to the number of resonating pieces of microstrip in the device: The lower the loss per piece, the more pieces are possible. It is common to fabricate 19-pole filters out of $YBa_2Cu_3O_7$ films. These filters operate at a center frequency of 900 MHz with a bandpass of 25 MHz and create less than a 1 dB of insertion loss. Such filters can be extremely important in the cellular communication industry, where efficient use of an allocated frequency band without cross-talk to other channels is of central interest. The issues involved with having to cool the superconducting filters be-

Table 3. Typical material properties for both low- and high-T_c superconductors important for devices. These numbers should be taken only as a general guide, since growth and processing conditions can affect them. Because $YBa_2Cu_3O_7$ is anisotropic, it is necessary to specify λ and ξ for each crystallographic direction. The a and b directions lie in the CuO planes; the c direction is perpendicular to them.

Material	T_c (K)	λ at $T = 0$ (nm)	ξ at $T = 0$ (nm)
Nb (low-T_c)	9.25	85	40
$YBa_2Cu_3O_7$ (high-T_c)	95	150 (a-b plane) 1350 (c direction)	3 (a-b plane) 0.2 (c direction)

low T_c in cellular communication base stations may not be overwhelming, since it is desirable to use cooled low-noise amplifiers in such systems anyway. Moreover, the inconvenience of cooling is offset by the economic benefits of using the smaller, thin-film superconducting devices instead of bulky, nonsuperconducting microwave cavities.

3.2 Nuclear Magnetic Resonance Spectroscopy Coils

Obviously the reduced surface resistance raises the Q value for the superconducting microcircuit since the two quantities are inversely proportional. This fact has profound implications for high-resolution NMR spectroscopy. In typical systems, the way to increase signal sensitivity is to use larger samples, average out the sample response over more measurement iterations, or perform the measurements in ever higher magnetic fields (the best typical systems already use 9.4-T superconducting magnets). An economically viable alternative, however, is obtained by using $YBa_2Cu_3O_7$ superconducting coils both to excite the rf radiation into and to detect it from the sample. With superconducting coils that have Q values exceeding 10^4 at temperatures of 25 K, it becomes possible to demonstrate an increase of the signal-to-noise ratio of 4 times or more. Such superconducting NMR probes are commercially available and can be retrofitted into existing NMR systems. Again, the attendant cooling issues are not of central concern from either an economic or engineering viewpoint; such cooling can already exist for low-noise amplifiers in the system. The increased probe performance also justifies the cooling requirements.

3.3 Microwave Delay Lines

Microcircuit delay lines are another obvious application for passive superconducting devices. First, the power attenuation along a superconducting stripline, $2\alpha = R_0\sqrt{C_0/L_0}$ (C_0 is the capacitance per unit length), is greatly reduced from that of a Cu stripline. This allows for greater line lengths. More importantly, the signal phase velocity $u_p = 1/\sqrt{L_0C_0}$ is frequency independent in a superconducting plate, unlike that in a thick Ohmic plate. This is simply because the penetration depth, unlike the skin depth, does not depend on frequency. Thus electrical pulses moving on a superconducting line hold their shape better, again conducive for longer delay lines. In addition, the nondispersive nature of the line allows for tighter timing between successive incoming signals. Indeed, from an engineering viewpoint, the reduction of signal dispersion is as important as the reduction of surface impedance in many superconducting microstrip devices.

4. SUPERCONDUCTING WEAK LINKS

Because all the itinerant electrons in a superconductor exhibit correlated motion, the usual wave–particle duality normally associated with a single quantum particle can be applied to the entire ensemble of Cooper pairs. Thus, there is a spatiotemporal phase associated with the ensemble that characterizes the supercurrent flowing in the material.

If the overall electron correlation is broken, this phase is lost, and the material is no longer a superconductor. However, there is a broad class of structures, known as *weak links,* where the correlation is merely perturbed locally in space rather than outright destroyed. Colloquially, we say that the phase "slips" across the weak link to acknowledge the perturbation.

The unusual properties of this phase slippage were first investigated by Brian Josephson and constitute the central principles behind superconducting electronic devices. Josephson found that the phase slippage could be defined as the difference between the macroscopic phases on the two sides of the weak link. This phase difference, denoted as ϕ, is related to the supercurrent i_s through and the voltage v across the weak link according to the Josephson equations

$$i_s = I_c \sin\phi, \tag{9}$$

$$v = \frac{\Phi_0}{2\pi}\frac{d\phi}{dt}, \tag{10}$$

where I_c is the critical (maximum) current of the junction and Φ_0 is the quantum unit of flux. (The flux quantum has a precise definition in terms of Planck's constant, h, and the electron charge, e: $\Phi_0 \equiv h/2e \approx 2.068 \times 10^{-15}$ Wb.) Intuitively, the Josephson effect can be envisioned as a small overlap of the quantum-mechanical wavefunctions between the two weakly coupled superconductors, with I_c reflecting the strength of the coupling.

As in the case of the two-fluid model in a bulk superconductor, the correlated motion of the superelectrons, here represented through the phase ϕ, manifests itself as an inductance. This is demonstrated by taking the time derivative of Eq. (9) and combining it with Eq. (10). Although the resulting inductance is nonlinear (it depends on $\cos\phi$), its relative scale is determined by $L_j = \Phi_0/2\pi I_c$, a useful quantity for making engineering estimates. For example, the energy scale associated with Josephson coupling is $L_j I_c^2 = I_c \Phi_0/2\pi$.

4.1 Elementary Model of Weak Links

It is convenient to model a superconducting weak link in terms of elementary lumped circuit elements. The resistively and capacitively shunted junction (RCSJ) model, shown in Fig. 1, is relatively simple and yet accurate enough to understand most practical aspects of weak-link behavior. The flow of superelectrons through the device is described by a nonlinear inductance as determined from Eqs. (9) and (10). A resistor R_n describes the flow of normal electrons through the device. Finally, a capacitor C_j represents a physical capacitance in the system, such as in a tunnel junction where two superconducting electrodes are separated by a very thin (typically less than 2 nm) insulating layer. Parasitic capacitance created by the fields around a device interacting with a dielectric substrate is also included in this lumped element.

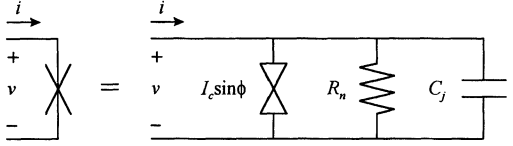

FIG. 1. The resistively and capacitively shunted junction (RCSJ) model of a Josephson device. If the shunted junction is envisioned as an inductance, many energy and time scales may be calculated as in elementary circuit theory. In a more sophisticated model, the resistive element would be nonlinear allowing for the subgap resistance to differ from that of the normal channel.

Because the weak link has been modeled from simple lumped elements, circuit intuition based on a knowledge of time constants is immediately applicable to understanding device behavior. For example, the quality factor of the circuit is

$$Q^2 = \frac{R_n C_j}{L_j/R_n} = \frac{2\pi I_c R_n^2 C_j}{\Phi_0} \equiv \beta_c, \tag{11}$$

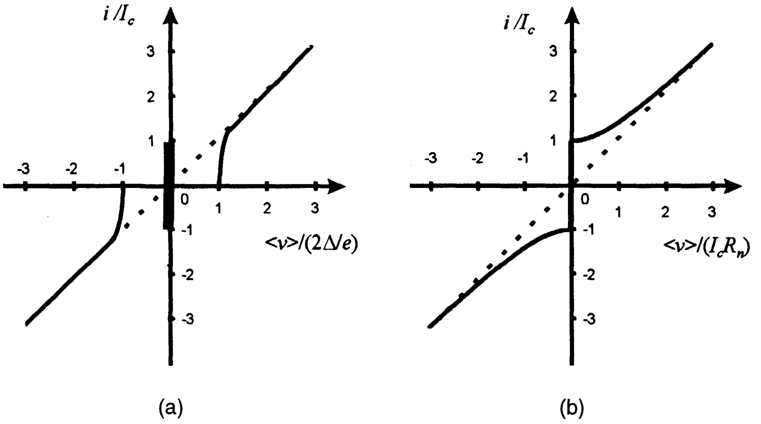
where β_c is known as the Stewart–McCumber parameter. Clearly, if $\beta_c \gg 1$, the capacitive time constant $R_n C_j$ dominates the dynamics of the circuit. As the bias current is raised from zero, no time-average voltage is created until the critical current I_c is exceeded. At this point, the junction switches to a voltage consistent with the breaking of the Cooper pairs, $2\Delta/e$, with a time constant $\sqrt{L_j C_j}$. Once the junction has latched in the voltage state, however, the capacitor has charged up, and the only way for it to discharge is to lower the bias current to zero again. As a result, a device with $\beta_c \gg 1$ will have a hysteretic current–voltage curve as shown in Fig. 2(a). Conversely, $\beta_c \ll 1$ implies that the capacitance of the device is unimportant, and so the current–voltage curve is not hysteretic [see Fig. 2(b)]. In fact, the time-averaged voltage $\langle v \rangle$ for such a RSJ device is

$$\langle v \rangle = iR_n\sqrt{1 - (I_c/i)^2} \quad \text{for } |i| > I_c. \tag{12}$$

In other words, once the supercurrent channel carries its maximum amount of current, the rest of the current is carried through the normal channel.

4.2 Fabrication of Practical Weak Links

There are many ways to fabricate a weak link. For example, microbridges can be fabricated from a single superconducting film where an intentional constriction, characterized by a size that is not much larger than ξ_s, is lithographically patterned. Because the Cooper pairs cannot stay correlated as they pass through the small constriction, the phase slips. However, using such a device in a commercial application is not realistic be-



(a) (b)

FIG. 2. The current–voltage characteristics of ideal Josephson junctions. Notice that the time-averaged voltage is the plotted quantity. (a) An underdamped, hysteretic junction. (b) An overdamped nonhysteretic junction. In both cases, the dashed line indicates the resistance R_n associated with the normal electrons.

cause the coherence lengths of practical superconductors are typically less than 40 nm. Using present lithographic techniques, this length scale puts unrealizable demands on the fabrication control and uniformity of a group of microbridges. Fortunately, several other geometries produce more manufacturable devices.

4.2.1 Low-T_c Devices

The low-T_c device used in most applications is the Josephson tunnel junction. The device consists of two superconducting electrodes separated by a very thin (typically 2 nm or less) insulating layer, resulting in a superconducting–insulating–superconducting (SIS) structure. A common, robust fabrication scheme for such devices is to deposit an Al/Nb bilayer, oxidize the Al *in situ* to form the insulating tunnel barrier, and complete the junction by immediately depositing another layer of Nb for the counterelectrode. Typically the Nb films are about 250 nm thick. It is possible to deposit these trilayer sandwiches reliably with critical current densities of up to 10 kA/cm^2, although experimental trilayers with critical current densities of up to 400 kA/cm^2 have been demonstrated. The junctions are then formed by patterning the trilayer sandwiches either with reactive ion etching or selective anodization of the Nb counterelectrode into an insulating oxide.

Nb SIS devices can be described by the RCSJ model with negligible conductance in the subgap region defined by $\langle v \rangle < 2\Delta/e$. At 4.2 K, a standard target J_c is 1 kA/cm^2 so that devices that are several square microns in size will have critical currents on the order of tens of microamperes. The gap voltage for such Nb devices is about 2.9 mV. The subgap resistance, defined as the ratio of the voltage to current at 2 mV, is about $40R_n$ in a well-made device. The specific capacitance is typically 4.5 μF/cm^2. The value of I_cR_n is expected to be about 1.8 mV. Of course, with increasing J_c all these values will change. It is routine to fabricate quality Nb Josephson junctions on silicon wafers up to 4 in. (~10 cm) in size.

4.2.2 High-T_c Devices

In contrast to the Nb trilayer, the most reliable form of a high-T_c weak link is the relatively simple bicrystal grain-boundary junction. This structure is fabricated by simply growing an epitaxial high-T_c film on a bicrystal substrate such as strontium titanate. The bicrystal substrate is formed by fusing two single-crystal substrates together at a specified angle. The grain boundary that forms in the epitaxial film over the fused region is a natural weak link for the oxide superconductors. (Such a technique would not work with the typical low-T_c superconductor because the grain boundary formed would not be a weak link.) The critical current of a bicrystal junction can be tuned by varying the relative angle of the two fused crystalline substrates. For $YBa_2Cu_3O_7$ applications, the optimum angle is about 24°. At 77 K, a 2-μm-wide

$YBa_2Cu_3O_7$ bicrystal device suitable for applications typically has a critical current of 10 μA and a resistance of 10–20 Ω. As a result, I_cR_n is 100–200 μV. Experimentally, the scaling law $I_c \propto R_n^{-2}$ is observed in high-T_c grain-boundary devices.

Although quite reliable from a production standpoint, the bicrystal junction can only be used in limited applications that involve superconducting devices that are linearly distributed along the grain boundary in the substrate. Moreover, any superconducting wiring that crosses the grain boundary would itself contain a weak-link device embedded in it. As a result, there has been a substantial effort to develop a different high-T_c device technology that is more suitable for circuit applications. The inherently short coherence length of the high-T_c materials makes them unlikely candidates for fabricated SIS junctions because the device properties are sensitive to the superconducting electrode properties within a distance of ξ_s of the barrier. As a result, it becomes difficult to control the quality of the important superconductor–insulator interface in the device. In addition, the angular momentum of a Cooper pair in the high-T_c materials may prevent the type of SIS tunneling expected from low-T_c devices.

These considerations have pushed workers to develop instead other types of high-T_c weak links, especially superconducting–normal–superconducting (SNS) devices, for circuit applications. The fundamental physics of both SIS and SNS junctions are similar: They both represent weak-link devices that operate because of overlapping superconducting wave functions from the two electrodes. There is an important difference, however: In a SIS junction, Cooper pairs must tunnel through a classically forbidden barrier (the insulator), while in a SNS device, Cooper pairs can be found for a time inside the metallic interlayer. Depairing in the normal metal occurs because the Fermi surface is smeared out by an energy kT. As a result, superconductivity is induced in the normal metal and the respective clean- and dirty-limit coherence lengths are given by

$$\xi_{nc} = \hbar v_F / 2\pi kT, \qquad (13)$$

$$\xi_{nd} = \sqrt{\xi_{nc} l / 3}. \qquad (14)$$

It is no coincidence that these expressions are similar to Eqs. (1) and (2), for the physics is essentially the same. The proximity of the normal material to the superconductor allows for a supercurrent channel to exist in the N interlayer. In general, the normal material will be in neither the clean nor the dirty limit. In such a case, the coherence length in the N interlayer is given by $\xi_n^{-2} \cong \xi_{nc}^{-2} + \xi_{nd}^{-2}$. Notice that the true value of ξ_n is always less then either the extreme limits given by ξ_{nc} and ξ_{nd}. Typical numerical values of the normal coherence length range from a few nanometers to about a micron depending on material and temperature.

High-T_c SNS devices are often made using an edge junction geometry. First, an epitaxial $YBa_2Cu_3O_7$ base electrode, typically 200 nm thick, is deposited and then covered by some insulator, often strontium titinate or yttria-stabilized zirconia. This bilayer is then patterned by ion milling. The patterning not only defines the base electrode but also forms the active edge of the device (the exposed edge of the $YBa_2Cu_3O_7$ film) because the incidence of the ion beam is approximately 60° from the normal of the film. A normal metal/$YBa_2Cu_3O_7$ counterelectrode bilayer is then deposited and patterned, completing the structure as shown in Fig. 3. Because the Cooper pairs are not classically forbidden from the normal material, the interlayer thickness of a SNS device can be much greater than that of a SIS device. A useful SNS device can have an interlayer thickness on the order of tens of nanometers, which relaxes fabrication requirements dramatically. This is the central appeal of developing SNS junctions for use in high-T_c circuits.

The conventional theory of the proximity effect in a SNS junction is well tested for low-T_c devices. It predicts a critical current that has a dramatic, exponential-like increase with decreasing temperature and is exponentially

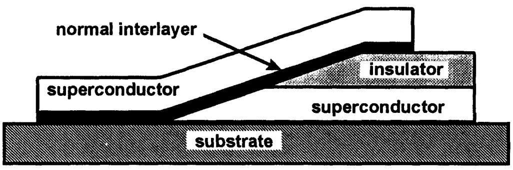


FIG. 3. SNS edge junction structure.

dependent on the thickness of the interlayer. Both of these observations hold in the clean and dirty limits and are a result of overlapping of the exponentially decaying superconducting wavefunctions in the N region. However, I_c of most high-T_c SNS junctions does not show the basic functional dependences predicted by conventional theory. For example, $I_c(T)$ in these devices is similar to the quasilinear behavior of grain-boundary junctions. This is most likely a result of pinholes in the N interlayer rather than an inappropriate application of proximity theory to high-T_c devices. The observation is justified by noting that if substituted forms of $YBa_2Cu_3O_7$, such as $Y_xCa_{1-x}Ba_2Cu_3O_7$ and $YBa_2Cu_{3-y}Co_yO_7$, are used as the N interlayer, then I_c as a function of temperature and interlayer thickness is reasonably consistent with conventional proximity effect theory. As a result, it appears that the N interlayer must be well matched structurally to the superconducting electrodes to grow properly and create a reproducible high-T_c SNS device.

Promising high-T_c SNS junctions for circuit applications can be made with an interlayer of $YBa_2Cu_{2.79}Co_{0.21}O_7$, typically 15 nm thick. Because this N material is a superconductor with $T_{cn} \approx 57$ K, the operating temperature of these SNS devices is restricted from below: $T_{cn} < T < T_c$. Typical critical current densities at 65 K for quality devices are 1.3×10^5 A/cm^2 so that junctions that are several microns wide have critical currents on the order of a milliampere. Corresponding specific resistances are approximately $4.8 \times 10^{-9}\ \Omega\ \text{cm}^2$. A large specific resistance is important because the devices should have I_cR_n values on the order of 500 μV at 65 K to be useful for circuit applications.

5. ACTIVE SUPERCONDUCTING DEVICES

Generally speaking, while we may think of passive superconducting devices as associated with microwave structures, active superconducting devices are usually associated with electronic applications. Moreover, active superconducting devices exploit the special quantum nature of the Cooper pairs more directly than passive ones. Thus the general applications of active superconducting devices are not merely an extension of existing technology but involve new concepts altogether.

5.1 Superconducting Quantum Interference Device

Just as the correlated motion of the superconducting electrons creates the frequency-independent Meissner effect in a bulk superconductor, so too the macroscopic quantum nature of superconductivity allows the possibility of a device whose output voltage is a function of a static magnetic field. If two weak links are connected in parallel, the lumped version of Faraday's law gives the voltage across the second weak link as $v_2 = v_1 + (d\Phi/dt)$, where Φ is the total flux threading the loop between the links. Substituting Eq. (10), integrating with respect to time, and again setting the integration constant equal to zero yields

$$\phi_2 - \phi_1 = 2\pi\Phi/\Phi_0, \tag{15}$$

showing that the spatial change in the phase of the macroscopic wavefunction is proportional to the local magnetic flux. From this discussion, it is apparent that a duality exists in how fields interact with the macroscopic phase: Electrical fields are coupled to its rate of change in time and magnetic fields are coupled to its rate of change in space.

Quantum interference, as represented by Eq. (15), can be exploited to make useful structures. Consider a dc superconducting quantum interference device (dc SQUID), shown in Fig. 4, which consists of two identical overdamped ($\beta_c < 1$) Josephson junctions connected in parallel and with wires into and out of the loop so that a biasing current i_{bias} can be injected symmetrically into the junctions. The current–voltage characteristics of the SQUID are identical in shape to those of the individual overdamped junctions with the critical current of the SQUID twice I_c of the junctions and the normal state resistance of the SQUID half R_n of the junctions. Applying a magnetic field to the SQUID induces a circulating current in the loop that will add to the dc bias current for one of the junctions and subtract from the dc bias current for the other one. As a result, the applied magnetic field will cause

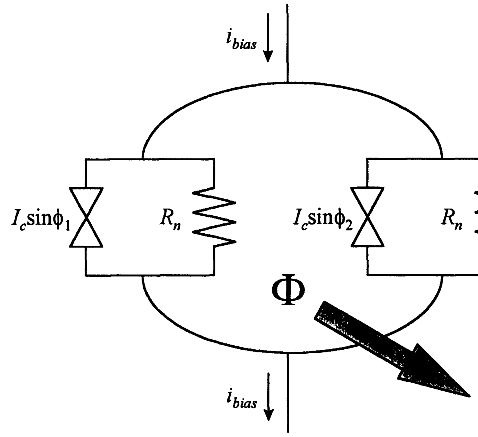

FIG. 4. A dc SQUID used to sense magnetic flux. The actual junctions are overdamped and have negligible capacitance as indicated in the model. The flux Φ threads the superconducting loop.

the junction where the induced and applied currents are adding to switch at a lower bias current. The magnetic field lowers the critical current of the SQUID from its maximum value of $2I_c$ while not influencing its normal-state resistance of $R_n/2$.

From Eq. (15) and the Josephson relations, we see that this magnetic-field modulation of the SQUID current–voltage characteristic is periodic in units of the flux quantum. Thus, the phase difference between the two junctions, and hence the SQUID critical current, is the same for all applied flux $\Phi + n\Phi_0$ where n is an integer. If we current bias the SQUID just higher than $2I_c$, then the change in magnetic field will produce a corresponding change in voltage across the SQUID. The SQUID is a magnetic flux-to-voltage transducer with a maximum peak-to-peak voltage modulation given by

$$\Delta\langle v\rangle = \alpha I_c R_n/(1 + \beta_L), \qquad (16)$$

where α is a constant of order unity, $\beta_L \equiv I_c L/(\Phi_0/2)$, and L is the SQUID loop inductance. Because the Φ_0–$\langle v\rangle$ transfer function is periodic in units of the flux quantum, a SQUID is an extremely sensitive magnetometer with an extraordinary dynamic range.

There are some engineering rules useful when designing a dc SQUID. First, the energy associated with the junctions should be much greater than that associated with thermal fluctuations to prevent unwanted switching: $I_c\Phi_0/2\pi \gg kT$. In other words, the junction critical current should be greater than 0.2 μA at 4.2 K and 3 μA at 77 K. Second, the energy of half a flux quantum in the loop should be greater than the thermal energy to prevent unwanted magnetic fluctuations: $(\Phi_0/2)^2/L \gg kT$. As a result, the inductance should be less than 18 nH at 4.2 K and 1 nH at 77 K. Note, however, that if L becomes too small, the SQUID will not couple to the applied field efficiently.

These criteria can be combined to reveal that in a well-designed SQUID, we expect $\beta_L \approx 1$. Usually L is chosen to satisfy this condition after I_c has been identified. To obtain the maximum voltage modulation, we see from Eq. (16) that we wish to maximize I_cR_n. There are two upper limits on this quantity, however. We do not want R_n so big as to become a major noise source in the SQUID. In addition, we do not want the product of I_cR_n and R_n so big as to violate the overdamped criterion $\beta_c < 1$.

In practice, SQUIDs are normally used in a feedback mode where their output is sent to a flux-locked loop, which in turn generates a current to create a small field to null the applied field. Such a scheme allows for accurate measurement of fluxes to less than $10^{-6}\Phi_0$ for a 1-Hz bandwidth. If the applied field is generated by a small current, it is then possible to use the SQUID as a precision voltmeter, capable of measuring picovolts. Such applications have been successfully demonstrated, and commercial SQUID systems are available in both low- and high-T_c technology. At present, magnetometers made from Nb SQUIDs operating at 4.2 K have an order of magnitude better field-noise performance than those based on $YBa_2Cu_3O_7$ bicrystal SQUIDs operating at 77 K. Nevertheless, $YBa_2Cu_3O_7$ magnetometers have improved in noise performance by three orders of magnitude since the discovery of the high-T_c materials and may soon provide a performance similar to that of Nb magnetometers.

5.2 Logic Circuits

Josephson devices have two properties that make them highly desirable for digital circuit applications: their switching speed is quite high, and their power dissipation is quite low. Originally, these properties motivated researchers to develop full-scale digital computers based on superconductor logic. The significant gains made in semiconductor technology since that time, however, have made general-purpose superconducting digital computers economically impractical. Nevertheless, niche high-speed applications, such as wide-band signal processing, and low-power applications, such as cross-bar switches, exist where superconducting circuits can still play an important role.

5.2.1 Latching Logic The first serious attempts to build digital circuits out of Josephson devices used underdamped junctions ($\beta_c \gg 1$). This choice is not surprising since the ideal hysteretic junction can go from a zero-voltage state, where all the current is carried by the superelectrons, to a finite-voltage, zero-current state, where the capacitor is charged and little current flows through the device. Thus we can envision a hysteretic junction as a switch: a logical 0 for the finite-current, zero-voltage state and a logical 1 for the finite-voltage, zero-current state.

The operation of the switch is straightforward. A bias current is applied to the device, $i_{\text{bias}} < I_c$. When an additional current signal flows through the junction, the critical current is exceeded, and the junction switches into the voltage state. By design, the load resistor on the junction is small enough that the switched state has minimal current. The switching time is estimated from the lumped-element model; first the current is steered from the inductor to the capacitor, and then the capacitor charges up. As a result, $\tau_{\text{switch}} \approx \sqrt{L_j C_j} + R_n C_j$. For a Nb SIS junction with a J_c of 1 kA/cm^2, the switching time is 9 ps. Higher values of J_c will increase the switching speed further. Resetting the device to its initial state requires a reverse current bias. Notice that some "amplification" occurs in the device because, if the bias current is close to the critical current, it will only take a small signal current to switch the junction. The power dissipated by the device is on the scale of $I_c^2 R_n$ and so is typically about a microwatt in a Nb device.

The central problem with latching logic is that the gates must be reset. The practical way to reset the devices in synchrony is to make the bias currents a common rf signal. Now, however, the designer must deal with clock skew; that is, the finite propagation speed of the clock signal to various parts of the chip. More importantly, the rf bias can interact in an unfavorable way with the internal nonlinear dynamics of the device itself (for example, those associated with the time $\sqrt{L_j C_j}$). This can leave the device at the end of the reset cycle with its capacitance charged in the reverse voltage state, an effect known as "punch through." To prevent this type of coupling, latching circuits typically are limited to clock speeds of a few gigahertz. This frequency is not high enough to make latching logic for general-purpose computing economically competitive with various present semiconductor technologies.

5.2.2 Single–Flux-Quantum Logic Overdamped, nonhysteretic junctions ($\beta_c < 1$) provide a way out of the reset problem because there is no significant capacitance to influence the device dynamics. Consider an overdamped junction, again current biased just less than I_c. A small signal current will switch the device into a finite-voltage state as before. Now, however, removal of the signal current will leave the junction in the initial superconducting, zero-voltage state. In a sense, the overdamped device is self-resetting.

Consider the dc SQUID. The time it takes for a single-flux quantum to pop into or out of the superconducting loop is equal to the switching time of the overdamped junctions. It takes little effort to envision the dc SQUID as a flux switch: a logical 0 for a loop containing no flux quantum and a logical 1 for a loop containing a quantum unit of flux. Thus we can view a logic based on overdamped junctions in terms of voltage pulses running around a circuit or, equivalently, as a circuit shuttling around flux quanta. The latter perspective lends its name to the architecture. In single–flux-quantum (SFQ) logic, the dc SQUID is the key lumped element.

SFQ circuits are typically built from Nb devices. Because standard Nb SIS junction processing is so robust, overdamped devices are made by externally shunting a SIS device. The Nb circuit is expected to operate at 4.2 K, and so a critical current of about 100 μA is chosen to minimize the effect of thermal fluctuations. The shunt resistance R_s is typically 1 Ω, much less than the value of about 18 Ω for R_n in such a device. From the lumped-element model, the overdamped junction switching time is about L_j/R_s or 3 ps in this case. As with the hysteretic device, τ_{switch} is quite fast. However, because the junction need not be reset, it is possible to take full advantage of this short switching time. Consequently, ultrahigh-speed performance on the order of 100 GHz could be possible. Moreover, the voltage-pulse nature of operation yields a power dissipation per device of about 100 nW. SFQ logic is therefore attractive because it is a low-power application that can be operated with dc, rather than rf, bias currents.

The dc SQUID loops found in SFQ logic are designed as previously described. For the Nb-based circuits discussed, a reasonable choice of L is about 15–20 pH. In general, to ensure that each SQUID loop contains either zero or one flux quantum, the I_cL product should be greater than Φ_0 but less than $2\Phi_0$.

SFQ logic is a natural choice for circuits using high-T_c materials for two reasons. First, latching logic does not scale well with temperature. As mentioned above, the required critical currents in an electronic application will scale linearly with temperature so that the devices will not switch because of thermal fluctuations. In latching logic, this implies that the power dissipated per device will scale as T^2, assuming a temperature-independent value of R_n. As a result, latching logic operating at 65 K will dissipate 200 times more power per gate than that at 4.2 K. In contrast, the power dissipation in a SFQ circuit only rises as T. Notice that the average voltage per cycle is determined by the nearly temperature-insensitive speed at which the flux quantum pops in and out of the superconducting loop. Thus, the average power dissipated by the overdamped junction will only be significantly affected by the size of critical current, which scales as T. The second reason why designers use SFQ architectures to implement high-T_c circuits is that only overdamped high-T_c devices can be fabricated as discussed above.

The higher operating temperature of high-T_c SFQ circuits, which makes them attractive, also causes problems. At 65 K, for example, I_c should be about 2 mA to minimize thermal fluctuations. This requires the SQUID inductance L to be about 0.5 pH if the condition $\beta_L \approx 1$ is to hold. The inductance per square of a $YBa_2Cu_3O_7$ stripline at 65 K, however, is only about 0.25 pH/square as can be estimated from Table 1. Thus, making a SQUID element for SFQ logic out of $YBa_2Cu_3O_7$ is not trivial since only a few squares of stripline can used for the loop. Practical designs will require engineering compromises, such as relaxing the choice of the magnitude of I_c, and engineering solutions, such as clever layouts. For instance, in video applications where ultralow bit error rates are not required, some thermal fluctuations can be tolerated and the magnitude of the critical current can be lowered. An example of a clever layout is to fabricate the SQUID loop out of two layers of $YBa_2Cu_3O_7$, one on top of the other, with a very thin insulating film between them.

Useful computational functions, such as high-speed sampling, multiplexing, and decimation, have been designed and fabricated in Nb-based SFQ technology. A special problem with such experiments involves performing the circuit validation tests at high speeds. Often, the designer will measure the circuit at some more modest speed, say 10 kHz, and check this measurement against a simulation. Nevertheless, experiments involving simple Nb SFQ circuits such as shift registers suggest that operation at frequencies of 60 GHz is possible. SFQ logic involving high-T_c devices is in its infancy, as the device fabrication technology has only just become available.

5.3 Three-Terminal Devices

Superconducting weak links are two-terminal devices and therefore cannot truly provide gain. Consequently, the use of two-terminal devices in an integrated circuit puts restrictions on fabrication tolerances of key parameters (such as I_c) that are more severe than those usually encountered in the semiconductor industry. There has thus been a strong desire to develop a superconducting three-terminal device that can deliver gain, high switching speed, and low power dissipation.

One class of three-terminal devices is analogous to bipolar transistors and treats the superelectrons and normal electrons as majority and minority carriers, respectively. In these devices, the superconductor would form the base of the transistor with normal metals or semiconductors forming the emitter and collector. Both ballistic and diffusive transport of the normal (minority) carriers in the superconducting base have been examined. Although such devices present major fabrication challenges, they can theoretically allow switching speeds approaching 1 THz.

Superconducting field-effect transistors form a second class of devices. Because the carrier density of high-T_c materials is relatively low, applied electric fields are not as easily screened as in ordinary metals. Consequently, one might expect a field-effect device to be attractive for high-T_c applications. Although gate-induced changes in transport properties have been demonstrated, thus far they are too small to warrant building a circuit from such elements.

Finally, there is the vortex transistor, which is unique to superconductivity. Here, the carriers are flux quanta that can be injected into the device from the magnetic field surrounding a separate current-carrying control line. As a result, flux can be independently introduced, for example, into a parallel array of overdamped junctions. When a bias current is applied to the array, the flux quanta will be shuttled from one end to the other, similar to the behavior in a SFQ shift register. Both the number of quanta moving through the array (given by the control line) and the speed with which they move (given by the bias current) determine the voltage across the device according to Faraday's law. These types of devices necessarily have a large area, thereby precluding their use as a common element in large-scale integrated circuits. Fortunately, most proposed applications of superconducting three-terminal devices do not require high integration density.

5.4 Mixers

In both space and atmospheric science, chemical constituents are typically identified from the electromagnetic spectrum created by molecular and atomic resonances. These spectra often have radiation lines with wavelengths of millimeters or less. For example, water will radiate at 325 GHz, carbon monoxide at 346 GHz. At the extreme end of the submillimeter spectrum there is an important radiation line associated with chemical processes involving atmospheric ozone at 2.5 THz. To detect such signals, it is desirable to mix the chemical spectral signal down to a more convenient frequency where traditional electrical components operate. A mixer is simply a nonlinear element that takes the incoming signal at a frequency ω_s and multiplies it with a local oscillating signal at a lower frequency ω_{lo} to produce a beat signal at an intermediate frequency $\omega_{if} = |\omega_s - \omega_{lo}|$.

The two charge-carrier channels in a superconducting device give rise to two classes of junction mixers. The first involves the interaction of the superelectrons (Cooper pairs) with the incident radiation to be downconverted. Suppose a dc bias voltage v_{bias} is applied to a Josephson weak link. Energy from rf radiation incident on the device can be used to assist the transfer of Cooper pairs from one side to the other. If a photon is absorbed by the junction, a Cooper pair can be moved from the low-bias side of the device to the high-bias side. A photon can also be emitted from the device, stimulated by the incident radiation. In this case, a Cooper pair is assisted toward the low-bias side of the junction. This photon-assisted transport occurs only at integral multiples of the Josephson frequency,

$$n\hbar\omega_J = 2ev_{bias}, \tag{17}$$

where, numerically, $\omega_J/2\pi v_{bias} = 483.6$ GHz/mV. Notice that the integer variable n can be either positive or negative corresponding to photon absorption or emission. The same relationship can be directly obtained from the Josephson relations, Eqs. (9) and (10), where a dc bias voltage will cause the magnitude of the supercurrent to oscillate at ω_J. Because Eq. (17) involves only fundamental physical constants, it provides a convenient and exceptionally accurate way to define a voltage standard on the basis of frequency alone.

From this simple picture, it is clear that rf radiation at a frequency ω_s will boost the supercurrent transport at bias voltages of $n\hbar\omega_s/2e$. Suppose that additional radiation, created by a local oscillator at a frequency ω_{lo}, is also incident on the device. The photons from this radiation will also assist Cooper pair transport, and so now the enhanced supercurrent transport occurs at bias voltages of $(n\hbar\omega_s + m\hbar\omega_{lo})/2e$, where m is an integer. Now consider a process in which a photon at frequency ω_s is absorbed at the same instant as a photon at frequency ω_{lo} is emitted. The supercurrent boost will come at a dc voltage associated with the intermediate frequency $\omega_{if} = \omega_s - \omega_{lo}$; the two rf sources have been mixed. To increase the probability of this particular photon process, the number of photons at ω_{lo} is increased by increasing the power of the local oscillator.

The enhanced-supercurrent mixing requires an overdamped device. Eliminating the effects of the junction capacitance prevents the incident rf radiation from coupling to the internal device resonances associated with the L_jC_j dynamics that would spoil the mixing. High-T_c weak links are a natural choice for Josephson mixers: Not only are they inherently overdamped but also they have displayed the highest I_cR_n values of any Josephson device ever made, exceeding 10 mV at 4.2 K. Indeed, the possibility of performing mixing at frequencies approaching 5 THz has motivated the application of high-T_c device technology in this area.

The second class of junction mixers involves the interaction of the normal electrons with the incident radiation. Again the quantum picture of photon-assisted transport is useful. Consider a SIS junction that has its supercurrent channel totally suppressed by a magnetic field. From the BCS theory, the occupied (unoccupied) energy states for the normal electrons are Δ below (above) those of the Cooper pairs in each of the superconducting electrodes. Incident radiation now assists the normal-electron transport across the energy gaps. As with the supercurrent case, the simultaneous absorption of photons at one frequency and emission of photons at another gives the nonlinear mixing effect. For negative biasing of the device to nearly $-2\Delta/e$, the maximum mixing frequency to assist normal carrier transport is $4\Delta/h$. Notice that again the incident rf radiation cannot couple to the internal device resonances associated with the L_jC_j dynamics because the inductance associated with the supercurrent has been suppressed.

SIS mixers have extremely good sensitivity and noise performance, even when compared to competing technologies. For example, Schottky diodes are nonlinear elements that can be used to mix signals in the same wavelength regime. However, SIS devices display sharper nonlinearities, as shown in the normal electron branch of Fig. 2(a). As a result, a superconducting mixer can provide greater sensitivity than a semiconductor one. In addition, superconductor mixers require much less local oscillator power. At $\omega_{lo}/2\pi \approx$ 100 GHz, a SIS mixer requires only about 10 nW of local oscillator power, about six orders of magnitude less than that for an equivalent semiconductor mixer.

For these reasons, Nb SIS mixers can be found on radio telescopes, such as the one in Owens Valley, California, and on high-altitude experiments where frequency detection in the range of 100–800 GHz is desired. (Cooling constraints are not an issue for these scientific applications.) At present, there is research activity to push toward the theoretical limit in Nb devices of 1.4 THz. Nb SIS mixers cooled to 4.2 K have been operated at 1 THz with a noise temperature 3 times better than that of GaAs Schottky diodes at the same frequency. Other ways of increasing the maximum mixing frequency is to use a low-T_c NbN SIS junction as the nonlinear element, which would theoretically allow mixing up to 2.2 THz. Indeed, the characteristics of low-T_c SIS mixers are so good that only their intrinsic frequency limit of $4\Delta/h$ makes high-T_c Josephson mixers attractive at all.

Finally, it should be noted that superconducting bolometers are also candidates for low- and high-T_c mixer applications. These devices are kept at temperatures just below T_c so that an incoming photon heats the superconductor up through its resistive transition. The corresponding large change in resistance is then detected. For small enough devices, the inherently nonlinear response of a bolometer can be made fast enough to be used in heterodyne applications. By definition, high-T_c devices have the advantage of operating at relatively high temperatures. As a result, a high-T_c bolometric mixer may be particularly useful when power constraints limit local oscillator power and prohibit cooling to ultralow temperatures, as on a satellite.

6. SUMMARY

Superconducting materials can be used to improve present systems dramatically by reducing loss and increasing system sensitivity. This is especially true with passive devices, such as microcircuit components. In contrast, active devices, usually formed from weak links, exploit the macroscopic quantum nature of superconductivity. Applications using active devices typically involve new concepts like superconducting quantum interference. In specific computational applications where ultrahigh speed is required, superconducting circuits may be economically competitive with semiconductor implementations. Although sophisticated circuit logic and ultrahigh-frequency mixing has been demonstrated using low-T_c materials only, high-T_c materials are the preferred choice for microwave applications. Indeed, commercial NMR spectroscopy probes built around $YBa_2Cu_3O_7$ coils are commercially available, and it appears that high-T_c superconducting microwave components may play a role in wireless communication systems. Finally, commercially available SQUID systems exist in both low- and high-T_c technologies.

In a brief article, it is only possible to hint at the many possible applications of superconductivity and the many issues involved in reducing those possibilities to practice. There are a number of important topics that are not covered in this article, including the voltage standard (see CONSTANTS, FUNDAMENTAL; UNITS), oscillators, bolometers, and applications of SQUIDs. In addition, device materials and fabrication is a constantly evolving subject. The reader is therefore strongly encouraged to consult the books and review articles listed below to appreciate applied superconductivity more fully. In addition, the peer-reviewed literature should also be examined, as superconductivity remains an active research field for both scientists and engineers.

INTRODUCTION

Superconductivity was discovered in 1911 by H. Kamerlingh Onnes, but it has taken nearly three-quarters of a century to make practical use of the phenomenon. The early materials investigated, mercury, lead, and tin, are type I superconductors and have a limited ability to carry high currents in the presence of a magnetic field. However, in 1930 type II superconductors were discovered by de Haas and Voogd. These materials showed promise of carrying very large current densities even in the presence of large magnetic fields. And over the following 30 years practical superconductors have been developed that can carry current densities of more than 1000 A/mm^2 in fields of more than 5 T. Equally important was the discovery of the correct theory of the phenomenon by Bardeen, Cooper, and Schrieffer in 1957, which placed the experimental facts on a firm theoretical basis. Commercially available conductors now make practical a wide variety of magnets useful for magnetic resonance imaging (*q.v.*) (MRI) systems, particle accelerators, thermonuclear machines, magnetic separators, and the levitation system for high-speed transportation. The operating temperature of these modern materials is generally about 4 K, and the cooling is provided by liquid helium (LHe). Some applications even make use of the high heat conductivity of superfluid helium below its lambda point. The delay in the deployment of superconductivity was undoubtedly tied to the difficulties in the metallurgy of the conductor on the one hand and the development of large cryogenic helium plants on the other hand.

The discovery of high-temperature superconductors (HTSs) in 1986 (see SUPERCONDUCTIVITY, HIGH-TEMPERATURE) has led to many exciting new prospects but, as before, practical conductor fabrication is facing many difficult problems. The major impact of HTSs will come about as the theory is developed and the practical problems are solved of fabricating these brittle, anisotropic materials into conductors possessing high current density and with mechanical properties suitable for the fabrication of magnets.

There are two important aspects of superconductivity that govern its practical applications. The first is the fact that the power loss in a conventional coil may be prohibi-

tively expensive. The second is the need for fields higher than 2 T. The currents required to reach these higher fields may be so large that a conventional coil would destroy itself through Joule heating. Examples of these considerations are seen in fusion magnets, large bubble-chamber magnets, and MRI magnets. For instance, the International Thermonuclear Test Reactor has a magnet in which the current per conductor is 39 kA in a field of 13 T. Some idea of the size of the magnet is obtained from the average length of a turn around the toroidal coil, which is almost 43 m, and from the total weight of the coil, which is 500 t. The stored energy is over 100 GJ!

Medical MRI magnets make use of another feature of superconductivity. If a magnet is charged to full current and then shorted with a superconducting switch, the magnetic field will remain constant, as the currents will continue to flow in a zero-resistance circuit. The design of such switches along with that of exceedingly low-loss cryostats and the ready availability of liquid helium has contributed greatly to the wide spread use of MRI for medical diagnostics.

The magnets we have been describing are large magnets with almost no restriction on the amount of space that can be taken up by the coil. However, particle accelerator magnets and magnets used for very high-field research bring in different problems. A typical high-energy accelerator such as the Tevatron or the Large Hadron Collider (LHC) being built in Geneva requires a uniform magnetic field over a transverse region of only a few centimeters. However, the radius of the orbit may be many kilometers. For instance, the Superconducting Super Collider (SSC) had a design circumference of almost 50 km, but the useful region of the magnetic field was contained inside of a 5-cm-diameter circle.

At a fixed energy, the radius of the machine is inversely proportional to the magnetic field, and typical fields are of the order of 4–9 T. Magnet design places a high premium on locating the conductor very close to the useful field region in order to minimize the amount of conductor required. To obtain high fields, current densities in the coil of 2000–3000 A/mm^2 are required. Some appreciation of this current density can be obtained when one remembers that typical house wiring has current densities of the order of a few amperes per square millimeter. Thus, modern accelerator magnets are completely dependent upon superconducting technology. Similar considerations apply to very high-field magnets used for research purposes, where a very compact coil is necessary if fields of 20 T or more are desired.

The design of superconducting magnets is heavily dependent upon the design of the conductor, and there are two problems that must be solved. The first is that the conductor may be unstable in a high magnetic field and spontaneously make a transition to the resistive state. The second problem involves protecting the cable from destruction by heating if such a transition should take place. The specific resistance of superconducting alloys in their normal state is much higher than that of copper, and at the current densities that have been mentioned above, the conductor would destroy itself from Joule heating within seconds. Both of these problems are solved by embedding the superconducting filaments inside a matrix of copper or other high-conductivity material. Successful fabrication of rather complex conductors by industry has been the key to the construction of successful superconducting magnets.

1. PROPERTIES OF SUPERCONDUCTORS

The discovery of superconductivity at Leiden was made possible by the fact that Kamerlingh Onnes had liquefied helium, which has a boiling point of 4.2 K. Using helium as a cryogenic fluid, he was able to achieve temperatures down to about 1 K, and mercury was the first superconductor to be discovered. But soon many other metals showed the same property, and Kamerlingh Onnes was quick to realize the potential use of this discovery for constructing magnets that could generate a very high field without the concomitant high energy losses experienced by magnets with a copper winding. Further experiments soon showed that the property of superconductivity was a function not only of temperature but also of the field in which the conductor was embedded. The superconducting property would simply disappear at some critical value of the magnetic field. This effect precluded the attainment of high-field magnets, since the self-field would turn the conductor into its normal state. It would be another 50 more years before high-field superconducting magnets were a reality!

1.1 Type I and Type II Superconductors

The early superconductors such as lead, tin, and mercury are called type I and are characterized not only by zero resistance but also by being completely diamagnetic. That is, they completely expel any magnetic field from their interior when they are in the superconducting state. The state is defined by the following parabolic formula:

$$B_C = k[1 - (T/T_C)^2], \tag{1}$$

where T_C is the critical temperature, B_C is the critical field above which the superconducting state vanishes, and k is a constant. All of the superconductors that were studied in this early period had T_C less than about 4 K and B_C less than 0.1 T.

In 1930, it was discovered by de Haas and Voogd that an alloy of tin and bismuth behaved in a different manner. This was the first so-called type II superconductor. On a microscopic level these materials allow the magnetic field to penetrate, and one observes bundles of flux tunneling through the conductor, each surrounded by a superconducting vortex of current. These vortices are not free to move but are pinned in the material by imperfections in the lattice. Such imperfections are called "pinning centers" and are controlled by the metallurgy of the fabrication process. The major developments in the type II superconductors have come through understanding the manufacturing processes that establish a high density of pinning centers in the lattice of the material. This will be discussed more completely in Sec. 2.3.

Type II superconductors are characterized by three variables: the current density in the conductor, *J*; the magnetic field at the conductor, *B*; and the temperature, *T*. A plot of *J* vs. *B* and *T* is shown in Fig. 1 for a typical NbTi alloy. The superconducting state disappears for values of *J*, *B*, and *T* above the surface. A subscript "*C*" is used to define the critical values on the surface. A plot of J_C vs. *B* at various values of fixed *T* is shown in Fig. 2. The values of *B* at which the various curves intersect the axis is an intrinsic characteristic of the alloy, and the shape of the curve below this point is an extrinsic property dependent upon the manufacturing process. At 4.2 K, the maximum field for NbTi alloy is about 9.9 T, and for Nb_3Sn, about 19 T. Nb_3Sn is clearly a better material for a high-field magnet; however, it is a material that has proved very difficult to fabricate into a usable conductor. As a result, when higher B_C is required, NbTi alloy is frequently employed at lower temperatures than the 4.2 K of boiling He. One can raise the maximum field to 13 T by reducing the temperature to 1.8 K. The magnets that are being constructed for the Large Hadron Collider (LHC) in Geneva rely on operating at temperatures near 1.8 K, and at this temperature LHe is below the Λ point and is superfluid. Not only is B_C increased, but the cooling is vastly improved by the high heat conductivity of the helium.

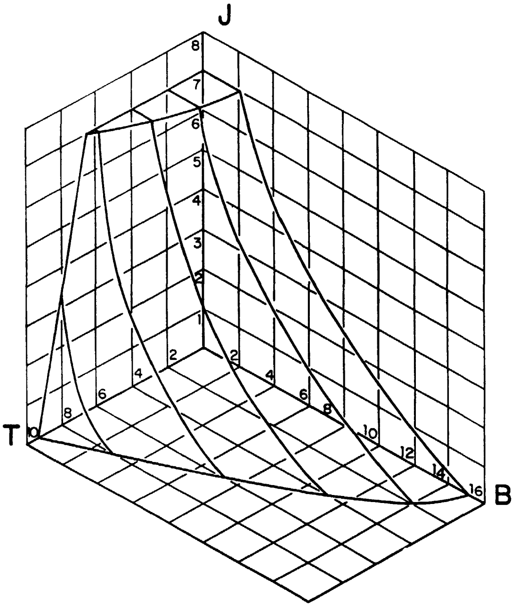

FIG. 1. The shape of the critical surface for a representative NbTi alloy. The material is superconducting only in the space under the surface. *J* is in kA/mm^2, *T* in K, and *B* in T.

In this article, two types of magnets will be used to illustrate the principles of superconducting magnet design. These examples will be solenoids and magnets for particle accelerators. There are many other uses for superconducting magnets, such as for fusion

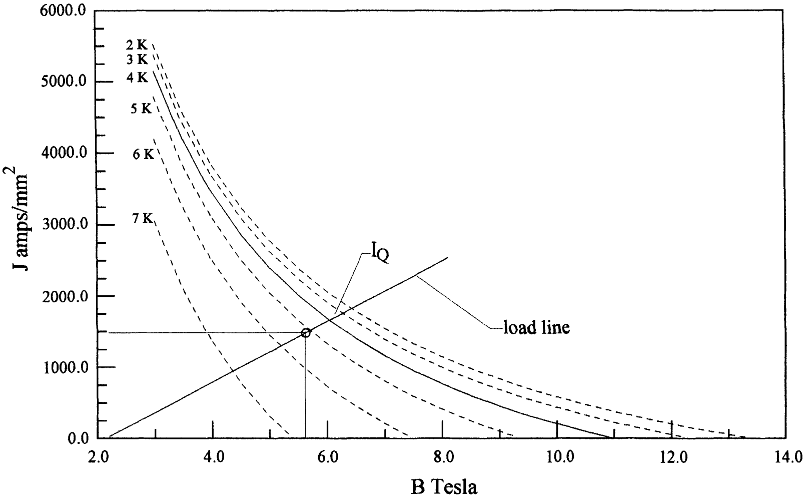

FIG. 2. This set of curves displays the properties of a typical NbTi alloy at a set of fixed temperatures between 2 and 7 K. The vertical axis is the current density in the superconductor, and B is the field in which it is immersed. The solid curve is for an ambient temperature of 4 K. Also shown is the load line for a typical magnet. If the ambient temperature is 4 K, then this magnet would quench at I_Q. The designed operating point is shown by the symbol "O."

devices, propulsion of ships, levitation and propulsion of trains, magnetic separators, and many other uses in instrumentation. However, the principles discussed here apply in general and serve as a tutorial approach to a complex subject. High-temperature superconductors bring in some new problems that are not discussed in this article, and the reader should consult other references (Shi, 1995; SUPERCONDUCTIVITY, HIGH-TEMPERATURE).

1.2 Load Line for a Magnet

The design of a superconducting magnet is dependent on the configuration of the conductor and its allowable current density. The required field shape will determine the geometrical placement of the turns, and the magnitude of the field will determine the current density. From the previous section, we have a relation between the field at the conductor and the limiting current density at the operating temperature. In general, the maximum field in the winding, B_m, will be higher than the required field B_0 in the useful region and must be calculated (frequently numerically) for the given winding geometry. We can plot the curve of B_m versus the current density in the winding as shown graphically in Fig. 2. This curve is called the "load line" for the magnet, and the conductor will turn normal at the point where the load line intersects the critical surface for the chosen operating temperature, which is shown as the solid line in Fig. 2. A successful design will have B_m less than the critical field at the chosen operating temperature and current density J_0, or a total conductor current of I_0. The maximum possible current is referred to as the "short-sample limit", I_Q, of the magnet. The term "short sample" refers to the fact that the characteristics of the conductor are determined using a short piece of the material, and it is assumed that this measurement will be representative of the whole winding. The safety factor I_0/I_Q can range from 0.9, which is typical for accelerator magnets, to 0.5 or less for magnets where a large stored energy could pose a real danger if the magnets should be accidentally driven into the normal state. As mentioned in the previous section, I_Q can be increased for a given conductor by lowering the temperature. For the large magnets that have been built so far, the two temperatures of choice are either that of boiling helium, which is 4.2 K, or superfluid helium at a temperature of about 1.8 K (Kingsbury and Van Sciver, 1995).

2. CONDUCTOR DESIGN

The design of a stable low-temperature conductor is a marvel of modern technology. The two materials that comprise the bulk of the commercially available conductor are NbTi and Nb_3Sn. The primary problem is to stabilize the conductor against the many sources of heat input that are present in an excited magnet. These consist of frictional motion of the winding, eddy currents in the conductor, small energy releases due to spontaneous reconfiguration of the field shape, and cracking of the epoxy insulation. Since the operating temperature is only a few kelvins, the heat capacity of the material is small and proportional to T^3. For instance, NbTi alloy has a heat capacity of only 3 mJ/cm^3 K at 4 K, almost 1000 times smaller than at room temperature. A secondary problem is that if the conductor goes normal, its resistance is very high and the Joule heating could immediately destroy it.

The solution to these two problems is to subdivide the superconductor into very fine filaments that are embedded in a copper or silver matrix and to assure that this matrix is in good thermal contact with the refrigerant. At low temperatures the electrical conductivity of copper may be over 100 times its room-temperature value, and this provides a means of carrying the current until the conductor can be recooled or the current reduced to zero by external means.

2.1 Flux Jumps

One source of heat input originates from small changes in the configuration of the magnetic field within the conductor. These changes are called flux jumps. To understand the process, consider a piece of superconductor in a magnetic field. The flux has penetrated, and there is some equilibrium distribution. However, Lenz's law states that during the charging process, currents will flow that resist the field penetration. When this opposing current density reaches J_C, the currents will no longer be able to resist further changes in the field, and more flux will enter the conductor. This reconfiguration of the flux in the conductor results in local heating. Another way of explaining the effect is that as the magnetic pressure builds up, it overcomes the strength of the pinning centers, and flux is forced into the conductor.

Now suppose we apply a small amount of heat dQ to a small volume dV. If no field were present, the temperature rise would be determined by the heat capacity. However, when a field is present, the temperature rise reduces the critical current J_C and consequently allows the field to change its distribution. This change in field distribution (redistribution of pinning forces) results in heating the conductor even more, and a runaway condition may exist that forces the conductor into its normal state. This is called a flux jump. The solution to the problem consists in subdividing the conductor into many fine filaments, which reduces the energy available for driving the instability. A detailed calculation shows that filament sizes of less than 100 μm are required. Figure 2 indicates that NbTi has a J_C at 4 K of about 2000 A/mm^2, and therefore a single 100 μm filament can carry no more than about 15 A. It becomes necessary to combine large numbers of filaments in parallel if the conductor is to be operated in a many-kiloampere range. The copper matrix structure provides the necessary mechanical support.

2.2 Eddy-Current and Hysteresis Losses

Additional sources of heat input are from eddy currents and from hysteresis losses. Eddy currents flow in conductors situated in a changing magnetic field. The source of particular concern here arises in multistrand cables where the strands are not insulated from each other and small loops can form using paths in the copper matrix. If the field changes, eddy currents will flow in these loops and produce local heating. These losses may be small, but, as was mentioned above, the heat capacity of the conductor is very low, and only a small amount of heat may increase the temperature enough to cause the conductor to quench.

Hysteresis losses are an additional source of heat that occurs in type II semiconductors. Consider a magnet that is driven up to its operating field and then returned to zero. It is found that there is a net energy loss in going around such a loop, much the same as for the hysteresis loss in a normal iron magnet. As the field increases, field lines are forced into the conductor, and as the field decreases, they move out. However, the pinning forces on the flux tubes make this an inelastic process, and heat is pumped into the lattice. This heat causes a small rise in the local temperature and must be carried away by the cooling system.

2.3 Conductor Fabrication

Satisfactory conductor construction depends upon the following considerations. First the superconductor must be divided into small filaments in order to insure flux-jump stability. Second, the filaments must be embedded in a copper matrix that can carry the current if the superconductor goes normal. The finished conductor must have good mechanical properties, as the forces in the magnet may be very high. Movement of the conductor can generate frictional heat, and strain in the conductor is known to reduce the J_C. Finally, there must be excellent cooling in order to insure stability as well as to remove any heat that is generated when the coil is excited.

2.4 NbTi Conductor

Niobium titanium superconductor construction is perhaps the easiest. Rods of the superconductor that are a few millimeters in diameter and up to a meter long are slid into a hole in a hexagonal copper rod. As many as 2000 rods are then closely packed together and inserted into a large copper cylinder that may be up to 12 in. (30.5 cm) in diameter. This assembly is heated and then extruded under high pressure through a die that is of the order of 3 in. (7.6 cm) in diameter. The composite is drawn down through successively smaller dies until finally a strand of conductor is produced that may have a diameter of a millimeter or less. A cross section of this strand will reveal NbTi filaments that are a few microns across embedded in a copper matrix. A photomicrograph of the type of strand used in the Tevatron is shown in Fig. 3. The details of the drawing of the strand and its annealing schedule control the pinning centers and thus the shape of the $J(B,T)$ critical current surface. Major improvements in the current-carrying capacity and the yield of unbroken strand have resulted from extensive metallurgical studies of the properties of this composite over the last 20 years.

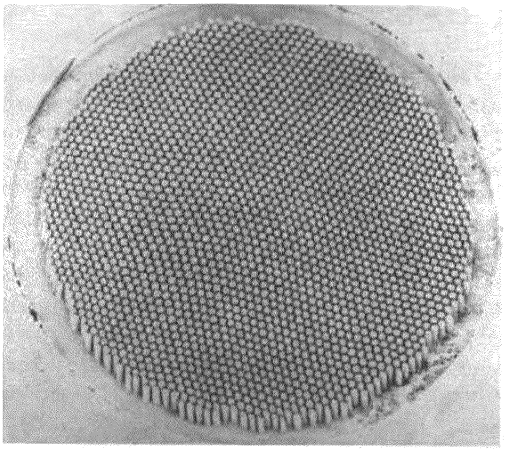

FIG. 3. Photomicrograph of a strand of superconducting wire used in the Tevatron. The copper matrix, which is about 0.6 mm in diameter, has been etched back, and the individual NbTi filaments, which are less than 10 μm in diameter, can be seen. At 4 K this strand will carry about 200 A in a magnetic field of 5 T.

Many smaller magnets are wound directly from the insulated strand. However, if currents larger than a few hundred amperes are required, the strand is woven into cable, which may have 30 or more strands. As the strands are cabled, they are twisted about their axes with a pitch of the order of a few centimeters in order to decouple the strand from any magnetic field in which it is embedded. In addition, the strands in the cable are wound in a spiral fashion around the axis of the cable in order to decouple the cable itself from the magnetic field. For particle accelerator magnets, this cable is flattened into a rectangular cross section that is a few centimeters wide and a few millimeters thick. It is insulated with Kapton film that is coated with epoxy on the side away from the conductor. After the coil is wound, a heat treatment bonds the epoxy-coated insulation together, forming a structure that can be handled.

However, other treatments of the strand are possible. Large solenoids have been constructed from a conductor manufactured by extruding very pure aluminum around the strands. A cross section of this conductor then shows a rectangular aluminum shape with a strand embedded inside. The shape provides a good means for mechanically supporting the forces on the conductor, and the additional cross section of very pure aluminum provides a large amount of very low-resistivity conductor to carry the current in case the coil should quench.

An additional technique that has been developed where space is not important is to incorporate the strand into a cable and then insert the whole cable into a stainless steel tube. Open channels are left within the cable so that LHe can then be circulated through the conductor. This technique is referred to as cable-in-conduit or CIC conductor and has been used for the large thermonuclear device magnets (Williams *et al.*, 1994; Mitchell *et al.*, 1994).

2.5 Nb_3Sn Conductor

Nb_3Sn conductor presents a new set of special problems. All of the preceding considerations apply, but in addition, the conductor is very brittle, and the filaments can easily fracture when the conductor is wound into a coil. As a result, the conductor is formed of unreacted niobium and tin. The billet is formed as for NbTi, but the niobium is enclosed in a bronze alloy instead of pure copper. The bronze provides a source of tin for forming the final alloy. The billet is then extruded and drawn into strand, which is cabled and wound into a coil. After the coil has been formed, it is then heat treated and the Nb_3Sn formed *in situ*. In order to do this, the conductor must be heated to about 650–700 °C for 175 to 200 h. The complexity of this process has limited its use to the fabrication of conductor for large rugged coils that can withstand the rigors of this heat treatment.

Nb_3Sn conductor is also being fabricated in the form of a thin tape that may be a few millimeters wide but only a fraction of a millimeter thick. This material is flexible and overcomes the obstacle of reacting the material in the completed coil. This conductor is particularly suited to solenoids where the topology of the winding does not require any tight bends and the forces are easily supported. There is a slight additional complication in that the material is anisotropic, and so attention must be paid to the field direction as well as magnitude during the design and subsequent construction of the coil.

2.6 Cryogenic Stability and Quench Waves

There are two general classes of conductor. Large bubble chambers and thermonuclear reactor coils are designed to be cryogenically stable. This means that there is sufficient LHe cooling to reestablish the superconducting state if the current should momentarily transfer to the copper matrix. This is arranged by having a sufficient amount of copper so that the Joule heating of the copper when forced to carry all of the current is less than the cooling provided by the LHe. This assures that if the temperature accidentally fluctuates above T_C, the cooling will be sufficient to reestablish the superconducting state. This type of conductor requires a large cross section of high-conductivity copper or aluminum. The problem is ameliorated by the fact that the conductivity of very pure copper or aluminum at 4 K can be several hundred times its value at room temperature.

As mentioned before, some magnets, such as particle accelerator magnets, place a high premium on coils that occupy smallest possible space. This requires a minimum amount of copper surrounding the superconductor, and if the conductor is driven into the normal state, the current flowing through the magnet will continue to heat it faster than it can be cooled. The spot that first turned normal will then spread longitudinally along the cable. This wave radiating away from the initial point is called a "quench wave." The initiating spot will be the hottest point, and the temperature rise can be calculated as follows. Consider a cable carrying a current I, and having a resistance per unit length $R(T)$ that is a function of the temperature. Let $C(T)$ be the temperature-dependent heat capacity per unit length of the cable. Then we can write the following equation:

$$I^2(t)R(T)dt = C(T)dT. \qquad (2)$$

This equation says that the Joule heat generated in a time dt only heats the cable and that no sources of external cooling are available. This is clearly a pessimistic assumption in that the helium in contact with the cable provides a major reservoir for cooling. By collecting together all of the terms that depend on temperature on one side, one can integrate the equation as follows:

$$\int_0^t I^2(t)dt = \int_{T_i}^{T_f} \frac{C(T)}{R(T)}\,dT. \tag{3}$$

The integral of I^2 on the left-hand side is under the control of the external power supplies, and the term on the right depends only upon the thermodynamic properties of the conductor and can be calculated from the known values of $C(T)$ and $R(T)$ and is only a function of the final temperature, T_f. This equation is extensively used in magnet design to calculate how fast the current must be reduced in order to limit the temperature rise of the conductor after a quench wave has started. Note that the point of highest temperature will be the point of the initiation of the quench, and the rest of the cable will be at a lower temperature. The low resistivity of cold copper helps to limit T_f. The designer also can control the ratio of the amount of copper to superconductor in the strand. This ratio is typically between 1.5 and 10.

2.7 Conductor Splices

Splicing conductor becomes necessary in order to obtain strands of conductor long enough for cable fabrication, for connecting coils internally within a magnet, or for connecting magnets in series. The strand itself can be ultrasonically welded, making a joint that reduces I_Q locally by about 30–40%. In a multistrand cable, this is only a small effect on the total cable current-carrying capacity but could be a serious defect in a single-strand conductor.

Conductor may be joined by soldering to the copper matrix that encloses the filaments. Frequently the joint is made by overlapping the two flat sides of the cable and soldering with lead tin solder. Joints in a 23-strand cable with an overlap of 30 cm can have a resistance of the order 10^{-9} Ω. Similarly, conductor coextruded with a pure aluminum jacket can be overlapped and welded along the edges. Both of these methods result in a compact splice that may be embedded smoothly within the winding. Other methods have been developed (McIntyre *et al.*, 1995). Careful attention must be paid to cooling because at currents of 10^4 A, a joint with 10^{-9} Ω will still dissipate 0.1 W. Coils for MRI magnets that operate in the persistent-current mode require careful attention to the joints, as a fractional magnetic field stability about 10^{-12}/s is desired. With an inductance of the order of 100 H, this requires a total coil resistance of less than 0.1 nΩ.

CIC cable used in large-volume magnets is a more difficult problem, and the joint is generally made in an external region, as the cryogenic circuit must also be kept intact. In all cases, the magnetic forces on the joint must be carefully calculated and provision made for absorbing them within the magnet structure.

3. LARGE SOLENOIDS

We now examine two solenoids as examples of the design techniques that have been developed. Table 1 gives the parameters for a MRI solenoid and for a very large magnet being designed for one of the particle detectors to be used with the LHC at CERN. A brief description of these two magnets follows.

The first is the MRI magnet developed by General Electric for image-guided invasive procedures (Laskaris *et al.*, 1995). It consists of two sets of coils that are split axially by 56 cm in order to provide access to the central region. There is no return yoke, and the large axial attractive force between the two coil assemblies is absorbed by four stainless steel posts. The conductor is copper-stabilized Nb_3Sn tape, and there is a superconducting switch to short the magnet and place it in a persistent-current mode (Dorri and Laskaris, 1995). It is charged through leads fabricated from high-temperature superconductor (HTS) from an external power supply. There are two cryocoolers that maintain the temperature at 10 K, thus effectively utilizing the high T_C of Nb_3Sn.

The field is constant over a sphere of 20 cm diameter to 1.6 ppm at the center of the magnet. In order to achieve such high uniformity, the two main coils are subdivided into three sections, and the positions and numbers of turns in the individual sections

Table 1. Properties of two modern solonoids. The first is a cryocooled solenoid designed for interventional MRI applications. The second is a large detector magnet intended for use with the LHC at CERN. The table illustrates the extreme range of parameters possible with SC solonoids.

	GE-MRI	CERN CMS detector
B (T)	0.5	4.0
Diam. × length (m^2)	0.96 × 1.48	5.9 × 14
Inductance (H)	464	14
Current (A)	65	20 000
Stored energy (MJ)	1	2850
Conductor type and size	Nb_3Sn 3 × 0.22 mm^2	NbTi 61 × 22.3 mm^2
Stabilizer to SC ratio	6	~9
Cooling	Cryocooler, ~10 K	LHe, ~4 K

are then used to optimize the size of the uniform volume and minimize the conductor required. The final trimming of the field for uniformity is done with iron shims placed in the warm bore of the cryostat.

The coils are wound on two stainless steel forms and then impregnated with epoxy resin. The large hoop stress is absorbed by heat-shrinking stainless steel rings over the winding, which provides a large compressive force. This illustrates a technique commonly used to limit the stress excursions at the winding. In many cases the initial pressure is great enough so that there is no stress reversal when the magnet is cooled and excited. This insures that the support will not have microfractures, which can release heat and cause the magnet to quench. In all cases a careful 3D computer analysis must be made in order to ensure safe magnet operation during cool-down, normal operation, and abnormal operation such as during a quench.

The initial cool-down is accomplished using cryogens and takes about 5 days. The two cryocoolers maintain it at the operating temperature of 10 K and also allow for servicing. The total heat load of the 70-K shield and intercept is 49 W and at 10 K is 2.1 W. HTS leads using grain-oriented YBCO are intercepted at 70 K and are copper from that point to room temperature. The 10-K load of the leads is 0.2 W and the 70-K load is 11 W.

For contrast we next consider a solenoid being constructed for the CMS detector at CERN (Desportes, 1995). Larger magnets have been designed or built, but this example will illustrate the techniques used. The design problems are dominated by the large forces that must be safely controlled. In this example, the return yoke provides a massive structural element for supporting the coil. However, the very large hoop and axial forces within the coil package have required new techniques to be developed.

First, a four-layer coil is used in order to obtain the ampere-turns necessary for a 4-T field. In order to distribute the stress uniformly through the four layers, it is required that each layer must support its own hoop stress. However, the customary superconductor coextruded with ultrapure aluminum is not strong enough, and an additional layer of high strength alloy is used to reinforce the conductor. The uniform stress distribution is necessary to keep the epoxy-insulation matrix from fracturing under excitation.

The coil is fabricated in four sections that are 3.35 m long and have 146 turns each, wound on the inside of a 50-mm-thick Al alloy cylinder before vacuum impregnation with epoxy. The four coils are then assembled in a common cryostat. Indirect cooling of the coil is accomplished by flowing LHe through a closed circuit thermally bonded to the outer aluminum shell. The support for the coil in the cryostat requires care in design. If the coil is exactly centered relative to the iron flux return, the net axial force is zero by symmetry. However, a small displacement can result in large magnetic forces, and the elastic constant of the support must be great enough to ensure stability. However, a very stiff support requires structural members of large cross section with a resultant high heat loss. Instrumentation to measure the forces on the support system during excitation can help to minimize the off centering and maintain an acceptable margin of safety while utilizing a less massive support system.

Quench protection is accomplished by dumping the energy of the coil into an external resistor. Equation (3) is used to control the maximum temperature reached by the conductor. However, as pointed out, this equation gives an upper limit since, in general, a quench wave will spread through the coil structure and shorten the discharge time by increasing the total circuit resistance.

4. ACCELERATOR MAGNETS

Superconductivity has played a dominant role in the design of high-energy particle accelerators. We will discuss the magnets for these machines in detail, as they provide many illustrations of the construction techniques that have been developed for magnets over the past 20 years. The size of an accelerator at fixed energy is determined by the radius of curvature of the orbit. Thus, a premium is placed on bending magnets with a high magnetic field. However, the forces within the magnet are proportional to B^2, and the complexity of the support system for magnetic fields over 10 T rapidly increases the cost. Studies show that the cost of a machine has a flat minimum for fields around 8–9 T. Part of this cost is due to the extreme accuracy required for the field shape. For fields greater than 2 T, the shape is no longer determined by the shape of the iron but rather by the accuracy of the coil dimensions, and winding tolerances of the order of 20 μm are not uncommon in modern accelerator magnets.

A large part of the cost of the magnet is due to that of the superconductor, and hence the amount of superconductor is minimized by operating at 90–95% of I_Q. As a result the magnet becomes very sensitive to any source of heat input such as conductor motion, beam loss, etc., and a great deal of attention must be paid to magnet protection. With this short introduction, we now examine some of these points in detail.

4.1 Coil Configuration

For the main bending magnets, one desires a uniform vertical field. In practical terms, this requires that the field be constant to an accuracy of one part in 10^4 over a central region of the magnet cross section, which may be several centimeters in size. The field in a long magnet is essentially two dimensional, and at any point (r,ϑ) the field in the vertical direction, B_y, and in the horizontal direction, B_x, can be written as

$$B_y = B_0\left[1 + \sum_{n=1}^{\infty}\left(\frac{r}{r_0}\right)^n (b_n \cos n\theta - a_n \sin n\theta)\right], \tag{4}$$

$$B_x = B_0\left[a_0 + \sum_{n=1}^{\infty}\left(\frac{r}{r_0}\right)^n (a_n \cos n\theta + b_n \sin n\theta)\right], \tag{5}$$

where r_0 is a reference radius that sets the scale and is customarily taken to be two-thirds of the inner coil radius. Terms in the series are referred to as dipole, quadrupole, sextupole, etc. The a_n and the b_n are referred to as the skew and normal terms, respectively. The geometry of the coil determines which terms of the series are excited.

For bending magnets, only the first term in B_y is desired, and all the other coefficients should be minimized. Figure 4 shows a drawing of the Tevatron magnet, and the coil cross section can be seen surrounding the beam pipe. The coils subtend half angles with respect to the center of the beam pipe of β_1 and β_2 measured from the horizontal. The z axis, which is the direction of the beam, is out of the figure. Symmetry about the x and y axes will eliminate all of the a_n and the odd b_n. The two terms representing a sextupole and decapole, b_2 and b_4, can be eliminated by adjusting the two angles β_1 and β_2. Thus, the first harmonic after the dipole that appears is the 14-pole, which varies as r^6, and the field is approximately constant over the inner two-thirds radius of the aperture to better than one part in 1000. By placing additional spacers between the turns of the winding, more of the harmonics can be canceled, as was done for the magnets developed for the SSC, where the 14- and 18-pole terms were also eliminated.

In addition to bending magnets, accelerators and particle beam lines frequently require quadrupoles for focusing, and sextupoles or even higher multipoles for correcting errors or making the beam achromatic. Such magnets are designed in the same manner as indicated above for the dipole, but the coil will have additional poles.

The region outside of the coil is surrounded by iron in order to make a low-reluctance flux return. At the high fields, the

iron is frequently completely saturated, and the magnetic field will be a nonlinear function of the current. The properties of the iron are determined not only by its chemical composition but also by the fabrication processes in the steel mill such as rolling and heat treating. Thus careful control of the iron manufacturing process is necessary for accurate control of the magnetic field.

4.2 Forces

The forces in the coil are caused by the normal **J** × **B** forces. For a high-field magnet the field within the winding can produce large forces on the coil. For instance, a cable in a 10-T field carrying 10 000 A has a force of 10^5 N/m perpendicular to its axis. Another way of appreciating these forces is to note that the same 10-T field corresponds to a magnetic pressure of about 4×10^7 N/m^2.

For the coil that we are considering there are two components of force. The first is a large radial outward force on the coil, and the second is an azimuthal compression. This latter is caused by the magnetic field curling around the ends of the winding. These forces must be supported by an external structure that maintains the coil dimensions constant to about 1 part in 10^4. This support is referred to as a "collar" and is a nonmagnetic stainless steel yoke that provides a precision form for the coil and easily supports the radial forces.

The azimuthal compressive forces are particularly vexing. They cause the coil to compress and thus change the angles β_1 and β_2, which in turn affect the field shape. This problem is solved by collaring the coil under high pressure so that the mechanical forces are always greater than the magnetic ones. This guarantees that the contour of the collar will always be in contact with the coil and thus control its shape.

4.3 Magnet Fabrication

We can now describe the complete magnet. The coil is first fabricated from cable that has been flattened into a shape that has a thickness of about a millimeter and a width of 1 to 2 cm. It is wrapped in Kapton film that is 20 to 40 μm thick and serves as the electrical insulation. The outside is treated with a heat-sensitive adhesive. The coil is wound on a form, put into a high-pressure mold, and heated to set the adhesive. All of the dimensions of the components must be carefully controlled if the shape of the magnetic field is to be within tolerance. The coil after curing can be handled but is structurally rather weak.

A major invention for constructing the collars involved using laminations stamped from thin stainless steel sheet. Stampings can be made with very high accuracy (better than 10 μm) and with a very reproducible shape determined by a die. The industrial process is well developed and inexpensive. The collars are formed in two pieces that are assembled around the coil, pressed in a large press to the final dimensions, and then welded together. The heat conductivity of the stainless steel is so low that the welding does not damage the insulation of the cable.

The Tevatron uses a warm-iron flux return, as can be seen in Fig. 4. The iron laminations form a 10-in. (25.4 cm) diameter hole along the axis. The cryostat fits in this hole and holds the collared coil, which is $5\frac{1}{2}$ in. (14 cm) in diameter. The angular space between contains the vacuum jacket, inside of which there are layers of superinsulation, a liquid nitrogen shield of 77 K, and finally a LHe bath around the coil. The cryostat forms a pipe for the cryogens, and a chain of 16 magnets is cooled by the circulating liquid. The iron yoke increases the field by 1 T. The arrangement is awkward because of the mechanical complications caused by placing a very complicated cryostat in a small radial space. The advantage, of course, is that the large mass of iron does not have to be cooled to 4 K.

The electron–proton collider, HERA, at Hamburg uses a similarly collared coil, but it is surrounded directly by the iron return yoke, which is therefore at 4 K. Modern refrigerators are able to cool the resulting large mass to LHe temperature in a reasonable time (days), and there is a big advantage in being able to use the iron to help support the radial forces exerted by the coils on the collars. The vacuum cryostat then surrounds the whole mass.

The new accelerator being built in Geneva, the LHC, is a 14 × 14-TeV proton–proton (*pp*) collider that has evolved still further (Perin, 1995). A *pp* collider requires two rings to carry the two proton beams in opposite directions (unlike the Tevatron, which is a proton–antiproton collider and uses only a single ring). The two magnets are mounted near each other, as shown in Fig. 5. Since the field must be in opposite directions in the two apertures, the LHC uses a single iron return yoke enclosing both coils so that flux lines of one magnet return through the other, resulting in a very compact structure. This can be seen in the flux plot shown in Fig. 6. The operating field is 9 T, and the iron is carefully shaped so that as it goes

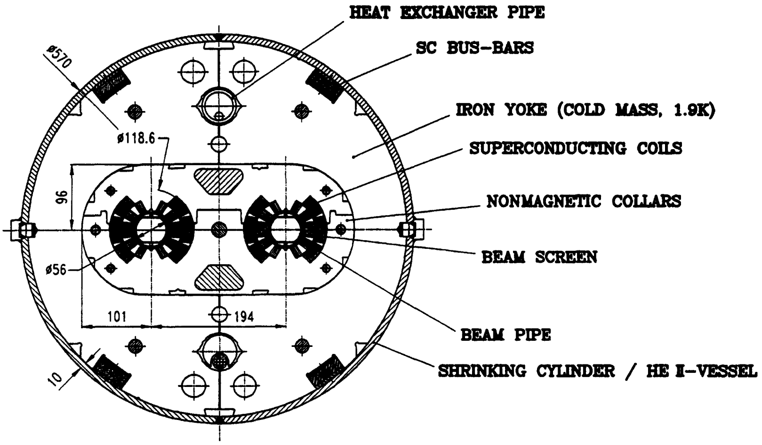

FIG. 5. Cross-section drawing of the LHC magnet. The cryostat surrounding the iron yoke is not shown. The magnetic flux goes up through the right-hand coil and down through the one on the left. The stainless steel collars that clamp the coil are nonmagnetic. The coils and iron yoke operate at 1.8 K. The dimensions are in millimeters.

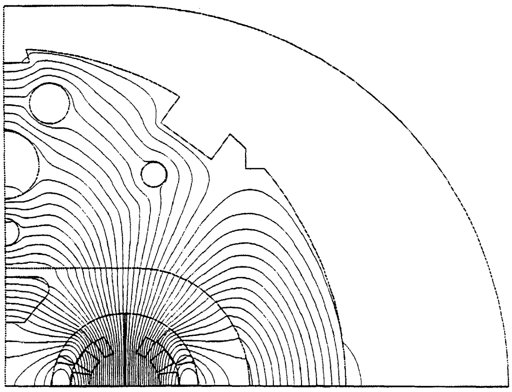

FIG. 6. Flux plot for the right-hand coil of the LHC dipole shown in Fig. 5. The flux going up through this coil is returned going down through the left coil.

into saturation the field in the two apertures remains uniform.

4.4 Training

The road to successful superconducting magnets has been plagued with the process called "training." A magnet designed to quench at current I_Q may only reach 50–90% of this value before spontaneously quenching on its first cycle of excitation. The second cycle and subsequent cycles will quench at increasingly higher values of current and asymptotically approach the value I_Q. The number of quenches to reach the limiting current can vary from 0 up to hundreds of cycles and is caused by heat generated from extremely small frictional motion of the conductors in the winding due to the increasing $\mathbf{J} \times \mathbf{B}$ forces during excitation. Each excitation cycle releases, in a ratchetlike fashion, the nonequilibrium forces that were generated during the initial coil fabrication until the coil eventually comes to an equilibrium state in which the ponderomotive forces are insufficient to break any more of the bonds.

This phenomenon has been particularly troublesome for accelerator magnets, as they are designed to operate very near I_Q, and since there may be several thousand magnets in a ring, it is imperative that all magnets operate at their designed value without training. The problem does not exist for cryostable magnets (as the conductor has enough cooling to return it to the superconducting state even if it is driven into the normal region) and is seldom a problem for large solenoids that are designed to operate with a very conservative safety margin. The source of the instability is due to the extremely small amount of heat that is necessary to drive the conductor from the superconducting state to the normal state as I approaches I_Q. Calculations and measurements both show less than a millijoule per gram of winding can cause a magnet to quench when it is operating at $0.9I_Q$. This small amount of energy is easily available from a number of sources. It may come from flux jumps within the conductor or from frictional motion of the conductors as the magnet is excited. A particularly bad source of heat can arise from fracture of the epoxy adhesive if a coil is completely impregnated. Accelerator magnets have thus avoided having epoxy in direct contact with the metallic conductor by completely wrapping it with a plastic film. Flux jumps are eliminated as previously described by proper conductor design. Finally, beam losses from the accelerated protons can easily deposit enough energy to quench a magnet, and so careful control of the orbit during all parts of the accelerating cycle is demanded.

Experience has shown that it is possible to prevent inelastic motion of the conductor, provided the mechanical pressure from the collaring operation is much larger than any of the magnetic pressures that the coil undergoes during excitation. Increases in collaring pressure are limited because if it becomes excessive, the turn-to-turn insulation will be ruptured. In spite of all of the above-mentioned difficulties, it is possible by careful design to construct large numbers of magnets that are stable at a current of $0.9I_Q$ and do not require training. However, in all cases, one must then be prepared to protect the coil if it starts to quench.

5. QUENCH PROTECTION

Once a quench wave starts in the conductor of a magnet, it will continue to grow as long as the current continues to flow. The temperature will rise according to Eq. (3) and must be limited to values that will not destroy the conductor. The method of disconnecting the power supply and connecting a resistor across the coil terminals works for a solenoid but does not work for an accelerator, for there may be hundreds of magnets in series, each storing one or more megajoules of energy. A different protection scheme is used. The offending magnet is first shorted after an electronic monitoring circuit detects a resistive component in the voltage. All of the energy in the magnet will now be absorbed in its winding. If the quench does not spread very fast, the energy may be deposited in only a few meters of the conductor with destructive results. However, a second mechanism can come into play. As the conductor heats, it can become hot enough to cause adjacent turns to also turn normal. If the thermal conductivity between turns is high, the whole winding may turn normal, and the energy will be deposited in a large mass. The resulting temperature rise for the coil may be less than 100 K. If the thermal conductivity is not high enough to spread the quench spontaneously, a second technique can be used. Each magnet is equipped with a heater that is thermally coupled to the coil. In the event a quench is detected, a pulse of current is supplied to the heater, which turns the whole winding normal. The amount of heat required is rather small, and the energy necessary for this pulse of current is stored in a large capacitor connected to a transistor switch.

6. COOLING THE MAGNET

Various techniques are used for cooling magnets, and the technique chosen is highly dependent on the anticipated heat load (see CRYOGENICS). MRI magnets for medical purposes can have very low losses as they are fixed-field magnets that are placed in a very low-loss cryostat and may even have the charging leads disconnected after the magnet is at full field. Pulsed magnets for large accelerators or the confinement magnets for thermonuclear machines must have large amounts of heat removed from the winding. The heat is generated by high-energy particles interacting in the coils and, in the case of pulsed magnets, from eddy-current and hysteresis losses as described earlier.

The simplest system is that used for the medical MRI magnets. The magnet is contained in an extremely low-loss cryostat, and LHe is supplied from a Dewar container. The total losses are so low that the He supply may only need to be serviced weekly or monthly. A second option for cooling low-loss magnets is a cryocooler (Laskaris *et al.*, 1995). This is simply a small closed-cycle refrigerator in which the last stage operates at a level of a few watts at 10 K. The 10-K operating temperature is nicely matched to magnets with Nb_3Sn coils and is now used extensively with medical MRI installations.

Large accelerator installations and thermonuclear machines require massive amounts of refrigeration to remove the heat generated within the magnets. Modern plants have an efficiency of the order of 0.5 MW of wall power per kilowatt of heat removal at 4 K. The cryogen is LHe at 4 K, but intermediate heat shields at 20–30 K or at liquid-nitrogen (LN) temperature may be used to intercept the room-temperature load and increase the overall Carnot efficiency. If superfluid He is required, it is generated from the 4-K liquid by passing it through a Joule–Thompson valve into a low-pressure region. This is the scheme that will be used at CERN for the LHC magnets.

7. CURRENT LEADS

A major heat load for the cryogenic system may be the leads that carry the current form the room-temperature power supply to the cold coil. If the superconductor were brought out of the cryostat to the power supply, its cold end would remain superconducting until reaching a point along the length where the temperature was greater than T_C, at which point it would become normal. It will conduct heat along its length and also generate Joule heat over the normal section. As mentioned before, once the superconductor goes normal, its resistance is very high, and the current is carried completely by the copper stabilizer. In general it is necessary to increase the amount of copper to enable the lead to safely carry the magnet current in a steady-state condition. Joule heating would dictate leads with a large cross section, but the Wiedemann–Franz law (see METALS AND ALLOYS, CONDUCTIVITY IN) guarantees that such leads will have a high heat conduction, and so careful attention to detail is necessary. In general, the design equates the Joule heating to the conduction heating. The combined source of heat is then carried away by passing cold vapor from the LHe through channels in the leads. Practical leads have a conduction loss to the 4-K system of the order of 1 mW per ampere of lead current.

HTS is being used to develop leads for a variety of magnets (Maehata *et al.*, 1995). Low-current magnets using cryocoolers and Nb_3Sn coils furnish an ideal application. As the intermediate shield is generally below 70 K, HTS provides an ideal conductor between this temperature and that of the coil. A section of the lead is made of bulk HTS. The field around the leads is frequently not high, and this provides an ideal use for the high-J_C, low-B_C material that is readily available. It is possible to make such leads with a heat leak that is only 0.1 mW per ampere of lead current, which is a factor of 10 better than the equivalent copper lead.

8. FUTURE DIRECTIONS

The use of low-temperature superconductor (LTS) materials has been completely dependent on the solution of some very complicated material design problems. At present, applications below 10 T are dominated by the use of NbTi, and even here cooling to 1.8 K is often employed. Nb_3Sn is used for higher fields, up to about 15 T at 4 K, or it can be used at lower fields with cryocoolers, thus utilizing its higher T_C to operate at 10 K. Improvements in both types of conductors continue to be made. Although B_C is fixed by the alloy and the operating temperature, J_C at a specified temperature and field can be optimized by controlling the details of the strand manufacturing process. The current-carrying capacity of NbTi at 5 T has been more than doubled over the last 15 years, and further improvements may still be expected. Recently a new method of strand fabrication has been developed that allows much more control over the density, spacing, and size of the pinning centers. At present, these variables are controlled by the schedule of the heat-treatment and drawing process. This is time consuming and must be carefully monitored. In the new technique, so-called "artificial pinning centers" are directly introduced before the material is extruded, which allows more direct optimization of the conductor (Miura *et al.*, 1995; Scanlan *et al.*, 1994).

8.1 High-Temperature Superconductors

The greatest promise for the future lies in the domain of HTSs. Materials are now known with a T_C of 125 K, which is well over the boiling point of LN. This opens up an enormous role for these materials in the electrical power and transportation industries. In addition, some of the material shows B_C values that are in excess of 50 T, which is well beyond anything available at present. However, the development of practical conductor for use in large-scale magnets is fraught with a myriad of difficulties as HTS materials are anisotropic crystalline ceramics. Progress is being made, and we list below some of the differences that HTS magnets will have relative to LTS types.

1. The operating temperature is higher, which makes the refrigeration much easier and cheaper to construct. The economic advantage is enormous and will have a great influence on the practical applications, especially if it can be done using LN as a refrigerant. Since the temperature is higher, the heat capacity of the conductor is also much greater than for material at 4 K, which makes the magnets intrinsically less sensitive to small influxes of heat from the surroundings.
2. The promise of higher B_C points to the possibility of practical very high-field magnets. For instance, some materials exhibit a critical field of over 50 T when cooled to 4 K. At present, the highest fields are obtained from hybrid magnets. An example is the 45-T hybrid being constructed at the National High Field Magnet Facility at Tallahassee, in which a LTS coil is designed to produce a field of about 14 T and an inserted, water-cooled copper coil generates an additional 31-T field using 24 MW of power (Miller *et al.*, 1994). There would be an enormous advantage to eliminating the inner copper coil and its huge power supply and replacing it with a low-loss HTS coil with a very high B_C.

This is a rapidly changing field, and the best overview is obtained from studying the transactions of various conference proceedings such as the INTERMAG Conference series published under the auspices of the IEEE. Some examples can be seen in the list of references.

GLOSSARY

Collars: The stainless pieces that are placed around the conductor and that absorb the magnetic forces.

Critical Current, J_C: The critical current density beyond which the superconducting state disappears. It is a function of field and temperature.

Critical Field, B_C: The critical field beyond which a material is no longer in the superconducting state.

Flux Jumps: Spontaneous rearrangements of the flux inside the body of a type II superconductor.

I_Q: The maximum superconducting current that a conductor can carry at a given field and temperature as measured with a short sample of the material.

HERA: A proton–electron collider using superconducting magnets for the proton ring. It is located at the DESY Laboratory in Hamburg, Germany.

HTS: High-temperature superconductor.

LHC: Large Hadron Collider. This proton–proton collider is being constructed at CERN in Geneva. It consists of two rings of superconducting magnets with a maximum dipole field of more than 8 T that guide two counter-rotating beams of protons into collision with a center-of-mass energy of 14 TeV.

LHe: Liquid helium. The normal temperature is 4.22 K at 1.0 atm.

Load Line: The relation between the field at some chosen point in the magnet and the current through the winding. The point used is frequently the central field, but for winding design, the high-field point in the conductor is the relevant point.

LN: Liquid nitrogen. Its temperature at 1.0 atm is 77.39 K.

LTS: Low-temperature superconductor. Generally NbTi or Nb_3Sn.

MRI: Magnetic resonance imaging.

Pinning Centers: Defects in the lattice of a type II superconductor that anchor the current vortices surrounding the quantized bundles of flux.

Quench: Refers to some point in the magnet coil making a transition to the normal state.

Quench Wave: The propagation through the magnet winding of the normal state caused by the Joule heating.

Tevatron: The first proton synchrotron accelerator constructed using superconducting magnets. It operates as a normal proton accelerator to 800 GeV and as a proton–antiproton collider at 1.8 TeV c.m. energy. It is located at Fermilab in Batavia, Illinois.

Training: If a newly cooled magnet is repeatedly excited to its quench point, it is frequently observed that the series of peak currents will show an increase with cycle number. The magnet is said to be "training." A well-designed magnet will reach its short-sample limit with no training quenches.

Short-Sample Limit: A magnet is said to reach its short sample limit if the current can be increased to the value predicted from measurements on the current-carrying capacity of the conductor combined with the calculation of the high-field point in the magnet coil.

SSC: Superconducting super collider. The design was for a proton–proton collider operating at 20 TeV in the center of mass system. Construction was started in Texas, but it was canceled before completion. However, the magnet was developed and prototypes constructed and tested.

INTRODUCTION

The discovery of high-temperature superconductivity (HTSy) in 1986 (Bednorz and Müller, 1986) in $La_{2-x}Ba_xCuO_4$ at 35 K and in 1987 (Wu *et al.*, 1987) in $YBa_2Cu_3O_7$ at 93 K, above the boiling point of liquid nitrogen (77 K), ranks among the most exciting developments in modern physics, with profound implications for future technologies. Before 1986, the highest superconducting transition temperature (T_c) was 23 K in Nb_3Ge. Many people considered superconductivity a laboratory curiosity, available only at very low temperatures with the aid of either the rare and expensive liquid helium or the not-so-safe liquid hydrogen. By 1986, the field seemed to have reached full maturity. Low-temperature superconductors (LTSrs) found some practical uses, such as superconducting quantum interference devices (SQUIDs) for detecting electromagnetic signals too weak for conventional sensors, and superconducting magnets for generating extremely strong magnetic fields more efficiently than conventional electromagnets. Nonetheless, their low T_c made it difficult to realize the full technological potential of conventional LTSrs.

With the advent of HTSy, the situation changed drastically. The superconductivity community was revitalized by the challenge to account for the occurrence of superconductivity at these high temperatures and to understand the many unusual normal-state properties of the high-temperature superconductors (HTSrs). These materials raised hope that a wide range of applications could become a practical reality, and they generated great enthusiasm among scientists, engineers, and the general public. Conflicting and poorly reproducible results soon led scientists to uncover significant materials problems and to raise serious questions about the technological future of HTSy. The dedicated efforts of many scientists, fortunately, has yielded steady progress, which has resulted in renewed optimism. Data from different experiments and different laboratories began to converge after scientists synthesized high-quality samples. Advances in the material processing and engineering of HTSrs have attracted the attention of design engineers to consider device integration and system development. Many application concepts have now been demonstrated successfully with HTSrs.

This article focuses on issues relevant to HTSy technology. It will also include a brief account of other interesting aspects of HTSy to give readers a bird's-eye view of this fascinating, rapidly evolving field, which is still in its infancy. As this article is being written, new high-temperature superconducting (HTSg) compounds are being discovered, new theoretical models of HTSy are being proposed, and new applications of HTSy are being demonstrated.

The first section provides a brief history of HTSy, discusses the materials that demonstrate HTSy, and summarizes the macroscopic theory of superconductivity by Ginzburg and Landau and the microscopic theory of superconductivity by Bardeen, Cooper, and Schrieffer. The second section deals with the synthesis of the complex HTSg materials. The third section summarizes physical properties crucial both for understanding HTSy and for applying these interesting materials. The fourth section describes our current theoretical understanding. The fifth section presents the promises and criteria for the application of HTSg devices. The last section briefly describes future scientific and technological trends in the study of HTSy. Finally, several review articles on various aspects of HTSy are listed, following the bibliography.

1. GENERAL

The term "high-temperature superconductors" (HTSrs) refers to materials with a high transition temperature (T_c), where a superconductor undergoes a transition to its superconducting state on cooling, evidenced by a drastic resistance drop and a diamagnetic shift. In this article, the T_c of a superconductor can refer either to the temperature of the onset (T_0) or the completion (T_c) of the superconducting transition, with the former higher than the latter, although they both always represent temperatures below which superconductivity exists. The difference between the two definitions diminishes with improved sample quality. However, the operating temperature of a device made of a superconducting material is usually lower than its T_c in order to enhance the stability, the sensitivity, and the supercurrent carrying capacity of the device. For instance, the supercurrent carrying capacity of a superconductor increases from 0 at T_c to about 90% of its maximum value at $0.7T_c$. Before 1986, superconductors with $T_c > 10$ K, the highest for an element, could be considered HTSrs (Allen, 1982). Since 1986, the term has generally applied only to materials with $T_c > 23$ K, the record of the intermetallic compounds, or above 77 K, the liquid nitrogen boiling point.

Throughout the history of superconductivity, one main goal has been to find compounds with higher T_c's to make applications more practical. However, T_c has risen dramatically only since the discovery of superconductivity in cuprates in 1986, as shown in Fig. 1, with a present record T_c of 134 K at ambient pressure set in early 1993 (Schilling *et al.*, 1993) and T_0 of 164 K demonstrated in a compressed compound in late 1993 (Gao *et al.*, 1994a). Before discovery of the cuprate HTSrs, high T_c was found mainly in intermetallic compounds and alloys, many of which contained transition metals. Hundreds of such compounds and alloys were synthesized (Roberts, 1976) with T_c up to 23 K, largely as a result of the work of Bernd Matthias, the leader in discovery of high-T_c intermetallics until his untimely death in 1980. In 1953, he proposed the most successful guide to high T_c during the ensuing 33 years: the "Matthias empirical rule" (Matthias, 1953), which correlates T_c with the ratio of number of valence electrons to number of atoms, with the maximum T_c to occur at valence electron-per-atom ratios of $\sim$4.75 or $\sim$6.4. For instance, Nb_3Ge (T_c = 23 K) has a valence electron-per-atom ratio of $\sim$4.75. During this period, many other researchers also tried to raise T_c, primarily with experiments based on the BCS theory (Bardeen *et al.*, 1957), but they had little success.

Disappointed by unsuccessful attempts to raise T_c of intermetallic compounds above 23 K, Bednorz and Müller (1986) decided to examine metallic oxides. According to BCS theory (Bardeen *et al.*, 1957), a strong electron–phonon coupling will lead to a high T_c. Since strong electron–phonon interactions can happen in oxides, they reasoned that higher T_c might occur in nickelates and cuprates. Indeed, they detected a T_c up to 35 K, as evidenced by a resistivity drop, in mixed-phase

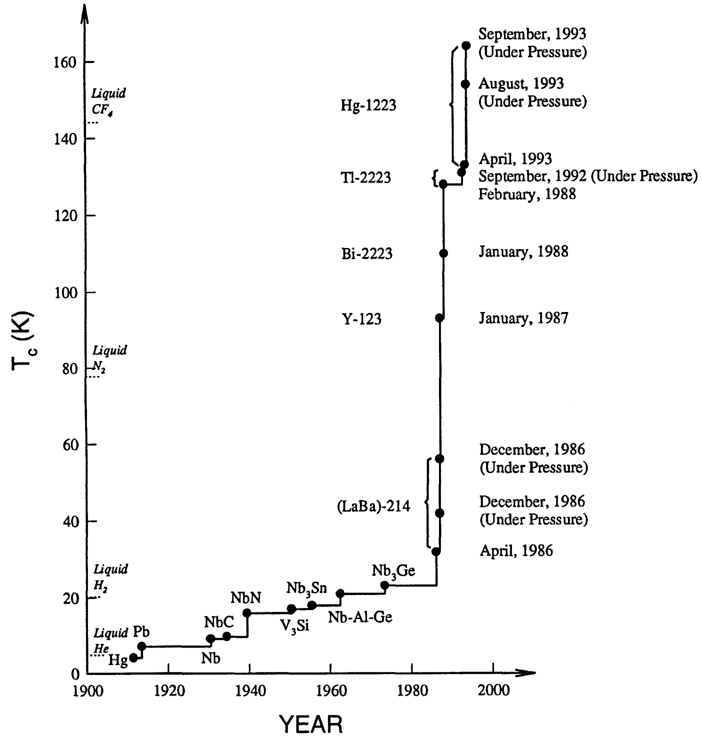

FIG. 1. Evolution of the maximum observed superconducting transition temperature (T_c) with time.

samples of La-Ba-Cu-O, and published their results in the September 1986 issue of *Zeitschrift für Physik* (Bednorz and Müller, 1986). The appearance of superconductivity at such a high temperature in an oxide surprised many experts. Partially because of its modest title, "Possible High T_c Superconductivity in the Ba-La-Cu-O System," their report did not attract much attention until the independent confirmations in December 1986 by research groups at the University of Tokyo and at the University of Houston. The Tokyo group identified the superconducting phase as $La_{2-x}Ba_xCuO_4$. Bednorz and Müller won the 1987 Nobel prize in physics a little over one year after the publication of their discovery.

In attempts to raise T_c, the Houston group made three interesting observations (Chu, 1987) in late 1986 and early 1987:

1. pressure enhancement of T_c to ~52 K in $La_{2-x}Ba_xCuO_4$ at an unusually high rate of ~1 K/kbar;
2. drastic resistivity drop at 80 K in mixed-phase La-Ba-Cu-O samples at ambient pressure, but not in $La_{2-x}Ba_xCuO_4$; and
3. a large diamagnetic signal persisting up to 90 K in a freshly made mixed-phase La-Ba-Cu-O sample at ambient pressure, but not in an aged one.

The observations suggested that a material different from $La_{2-x}Ba_xCuO_4$ with $T_c > 77$ K must be possible. The question was how to stabilize and identify the $T_c > 77$ K phase. By reviewing data at ambient and high pressures, the Houston group concluded that replacing La with chemically similar but smaller elements such as Y might help stabilize the high-T_c phase. In late January 1987, Wu *et al.* (1987) detected stable superconductivity at 93 K in a mixed-phase Y-Ba-Cu-O material. Several laboratories subsequently confirmed these results. Shortly afterward, the structure of the superconducting phase was identified as $YBa_2Cu_3O_7$ (Hazen, 1989). Within a few weeks, a series of isostructural compounds $RBa_2Cu_3O_7$ with R = Y, La, Nd, Sm, Eu, Gd, Dy, Ho, Er, Tm, Yb, or Lu was found (Hor *et al.*, 1987; Murphy *et al.*, 1987) to be superconducting with $T_c \sim 90$ K. A worldwide race to raise the T_c, to understand the science, and to make use of HTSrs was on.

Meanwhile, several research groups investigated the replacement of the trivalent rare earth element with trivalent Bi and Tl. Only a few weeks into 1988, Maeda *et al.* (1988) observed superconductivity above 100 K in mixed-phase Bi-Sr-Ca-Cu-O. Shortly afterward, the superconducting phases were identified as $Bi_2Sr_2Ca_{n-1}Cu_nO_{2n+4+\delta}$ with $n = 2$ and 3 (Hazen, 1989). Two weeks after the Tsukuba announcement, Sheng and Hermann (1988) reported a T_c above 120 K. The superconducting phases were immediately isolated and characterized (Parkin *et al.*, 1988) as $Tl_2Ba_2Ca_{n-1}Cu_nO_{2n+\delta}$ with $n = 1$, 2, and 3, with a T_c up to 125 K in the $n = 3$ member. In 1992, the T_c of this compound was raised to 131 K by the application of pressure (Berkeley *et al.*, 1993).

In March 1993, Putilin *et al.* (1993) synthesized $HgBa_2CuO_{4+\delta}$ with a $T_c = 94$ K. By adding Ca to the Hg-Ba-Cu-O material, Schilling *et al.* (1993) detected superconductivity at a new record T_c of 134 K in mixed-phase samples. The superconducting phases of $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$, where $n = 1$, 2, and 3, were separated (Chu, 1994) with the record T_c in the $n = 3$ member. An unusually large increase in the T_c of this same compound to 164 K at a pressure of 30 GPa was observed (Gao *et al.*, 1994a), demonstrating that superconductivity can exist above 160 K in cuprates. The challenge is to retain such a high T_c without pressure by chemical and/or other physical means to make this material practical for applications.

There are still no rules for the discovery of higher T_c's. The search for new superconductors has always required people with strong intuition, courage, and even faith. The hard work of those few has resulted in the exciting progress shown in Fig. 1.

1.1 High-Temperature Superconducting Materials

Since 1987, more than 90 nonintermetallic superconducting compounds were found with T_c above the 23 K record for the intermetallics. HTSrs belong to three families: cuprates, bismuthates, and fullerites. The cuprates at ambient pressures (Schilling *et al.*, 1993) have an anisotropic layered structure and a maximum $T_c \sim 134$ K; the bismuthates (Cava *et al.*, 1988) and fullerites (Hebard *et al.*, 1991) have a cubic structure with a maximum $T_c \sim 30$–39 K. We describe the basic crystal structures of the HTSrs at room temperature and refer readers to special articles (Chen, 1990) for the temperature-induced structural transformation and detailed microstructure in these compounds. We also briefly discuss the main features of HTSrs that are responsible for some of their unusual properties to be described later in Sec. 3.

1.1.1 Crystal Structures

1.1.1.1 The Fullerites. Compounds A_3C_{60}, with A = K, Rb, or Cs, belong to the newest family of HTSrs. They are formed by filling the interstitial sites of the face-centered cubic lattices of C_{60} (Fig. 2). The crystal structure is cubic and therefore isotropic, with an increasing lattice parameter as the atomic radius of A increases (Hebard, 1993).

1.1.1.2 The Bismuthates. The compounds $Ba_{1-x}A_xBiO_3$ (BABO), where A = K or Rb, display the perovskite structure (Fig. 3). The undoped semiconducting $BaBiO_3$ has a monoclinic symmetry, but doping transforms the superconducting monoclinic phase to an orthorhombic phase and finally to a superconducting cubic one. The cubic lattice parameter decreases with doping (Pei *et al.*, 1990).

1.1.1.3 The Cuprates: General. Cuprates account for the great majority of the known HTSrs and include all materials that superconduct above 77 K. They have a layered structure closely related to the perovskite lattice. The structure consists of CuO_2 layers with intervening metal and/or metal–oxygen layers that serve as the carrier reservoir. The CuO_2 layers are considered to be the active components of the HTSrs, displaying three different types of Cu–O coordination. They form arrays of CuO_4 squares, or they form CuO_5 pyramids and CuO_6 octahedra, respectively, by including an apical oxygen only above and both above and below the CuO_2 layers (Fig. 4). The intervening layers, which serve as the charge reservoir, may have much greater structural complexity than the CuO_2 layers. The crystal structures of the most-studied cuprate HTSrs are shown below (Hazen, 1989). Others are basically derivatives of them.

1.1.1.4 The Cuprates: 214 Compounds. The compounds $(R, R')_{2-x}A_xCuO_4$ exhibit a T_c up to ~36 K where R and R' are rare-earth elements and can be the same element, and the dopant A = Ba, Sr, Ca, Ce, or Th. Depending on the ionic radius of R and R', three structural phases, T, T', and T^*, are stabilized at 300 K (Fig. 5). They contain one CuO_2 layer per formula unit. The CuO_2 layer comprises arrays of CuO_6 octahedra in the T phase, CuO_5 pyramids in the T^* phase, and

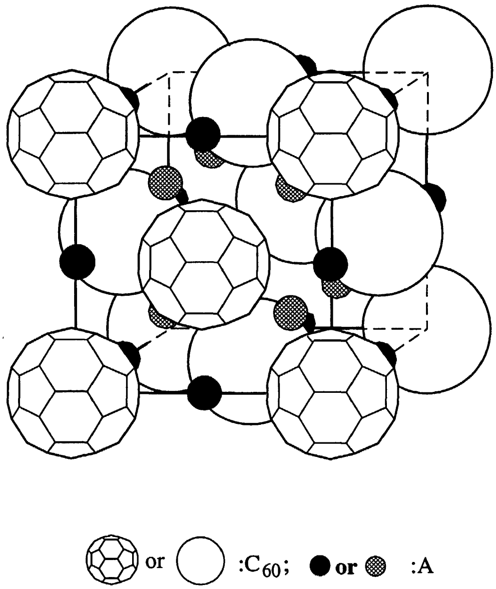

FIG. 2. The cubic crystal structure of fullerite HTSrs: A_3C_{60} (A = K, Rb, or Cs).

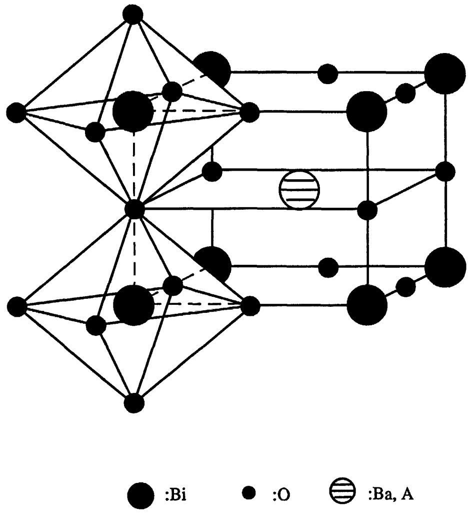

FIG. 3. The perovskite crystal structure of bismuthate HTSrs: $Ba_{1-x}A_xBiO_3$ (A = K or Rb).

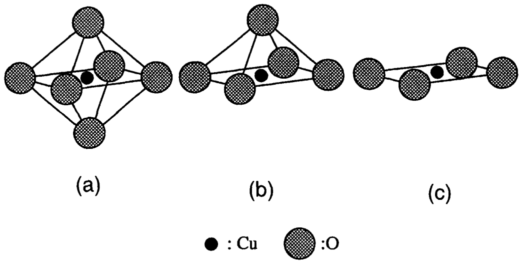

FIG. 4. Three types of CuO_2 layers displaying different Cu–O coordinations: (a) CuO_6 octahedron, (b) CuO_5 pyramid, and (c) CuO_4 square.

CuO_4 squares in the T' phase. These HTSrs display a tetragonal symmetry.

1.1.1.5 The Cuprates: R123 Compounds. $RBa_2Cu_3O_7$ (also known as RBCO) show a T_c up to ~100 K where R = Y or any of the rare-earth elements except Ce and Tb. The crystal structure of the 123 compound is orthorhombic (Fig. 6). It consists of two CuO_2 layers and one CuO-chain layer per unit formula. The oxygen in the CuO chain is only loosely bound. When the oxygen content is less than ~6.4, the oxygen atoms in the CuO chain lose their long-range order, and the compound becomes tetragonal and nonsuperconducting. $PrBa_2Cu_3O_7$ is superconducting only in thin-film form, and then only when Pr is partially replaced by Ca.

1.1.1.6 The Cuprates: Bi-, Tl-, and Hg--Based Compounds. The compound $Bi_2Sr_2Ca_{n-1}Cu_nO_{4+2n}$ [Bi-22(n − 1)n or BSCCO] displays a T_c up to ~120 K; $Tl_mBa_2Ca_{n-1}Cu_nO_{2+m+2n}$ [Tl-m2(n − 1)n or TBCCO] shows a T_c up to 125 K; and $HgBa_2Ca_{n-1}Cu_nO_{2n+2+\delta}$ [Hg-12(n − 1)n or HBCCO] exhibits a T_c up to ~134 K at ambient, where m = 1 or 2, n = 1, 2, 3, 4, ... The n represents the number of CuO_2 layers in the compound per unit formula. Figure 7 shows the crystal structures for the Tl-22(n − 1)n, Tl-12(n − 1)n, and Hg-12(n − 1)n for n = 3. Notice that the linear Hg–O coordination and the vacant site for oxygen in the HgO_δ layers of Hg-12(n − 1)n, which do not appear in other cuprate HTSrs, may be responsible for the record T_c of 164 K in Hg-1223 at 30 GPa. The crystal symmetry is either orthorhombic or monoclinic for Bi-2201, pseudotetragonal for Bi-2212 and -2223, and tetragonal for all Tl- and Hg-based compounds.

1.1.1.7 The Cuprates: Infinite-Layered Compounds. The compound $Sr_{1-x}M_xCuO_2$, where M = Ca, La, Nd, Pr, or vacancies, shows a T_c up to 100 K. These compounds can be considered doped members of

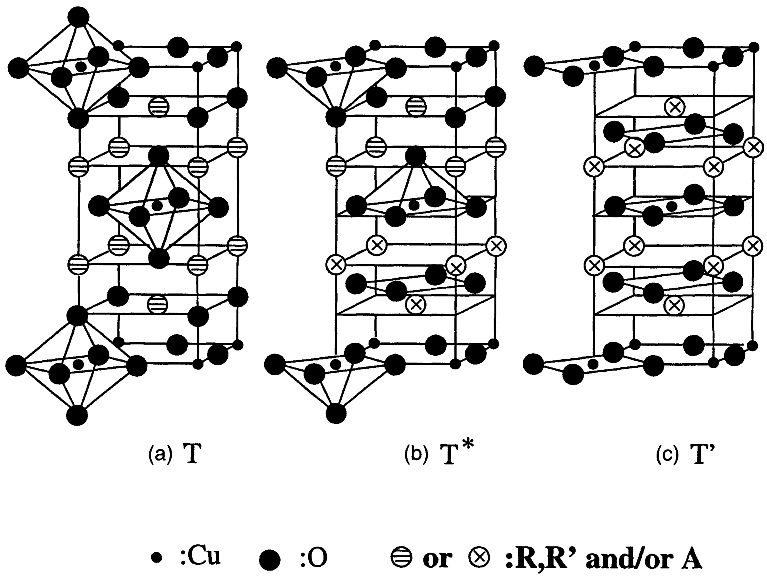

FIG. 5. The crystal structures of cuprate 214 compounds: T, T^*, and T' phases (R, R' are rare-earth elements and A = Ba, Sr, Ca, Ce, or Th).

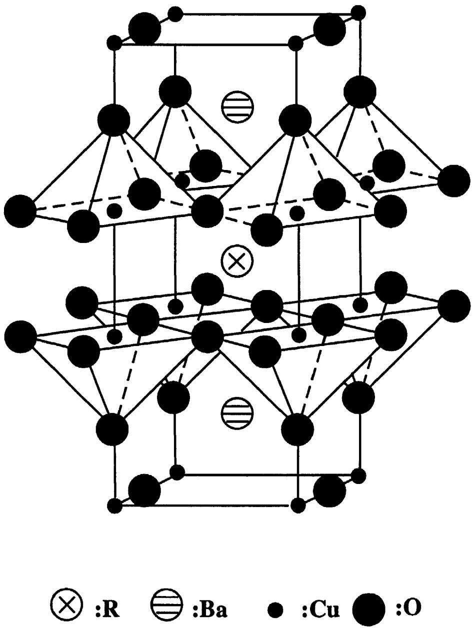

FIG. 6. The crystal structure of R123 compounds (*R* = rare earths other than Ce and Tb).

$SrCuO_2$, which belongs to the homologue series of $A_{n-1}Cu_{n+1}O_{2n}$ as $n \rightarrow \infty$, where A = Ca, Sr, or Ba. Therefore they are called the infinite-layered compounds. They consist of the simplest intervening Sr layers between CuO_2 layers with a tetragonal structure and may thus be considered the parent compounds of all HTSrs (Fig. 8). The superconducting phase can be stabilized in thin-film form by sputtering, or in bulk form under high pressures >2.5 GPa. The samples display a $T_c \sim 30$ K when doped with La, Nd, or Pr and up to 100 K when doped with Ca or vacancies. The detailed local structure of the $T_c > 30$ K phase is complex and has not yet been determined. Tantalizing resistive and magnetic anomalies suggestive of superconductivity up to 180 K have been reported (Li, *et al.*, 1992) in a thin-film sample of $Sr_{0.7}Ca_{0.3}CuO_2$ prepared by the laser MBE technique.

1.1.2 Main Features of High-Temperature Superconductors Similar to LTSrs, HTSrs below their T_c's display the same basic superconducting characteristics, i.e., resistivity $\rho = 0$, magnetic induction $B = 0$ when the applied field is smaller than the lower critical field H_{c1}, and electron pairing. However, HTSrs are rather different from LTSrs and pose serious challenges to the un-

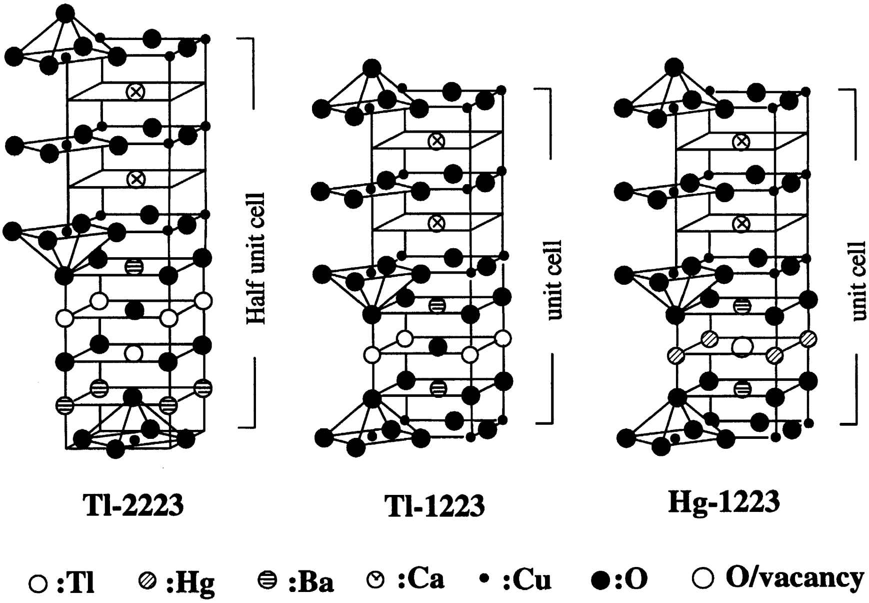

FIG. 7. The crystal structures of Bi-, Tl-, Hg-based cuprate HTSrs [Tl-22(*n* − 1)*n*, Tl-12(*n* − 1)*n*, Hg-12(*n* − 1)*n*] for *n* = 3 CuO_2 layers per unit formula.

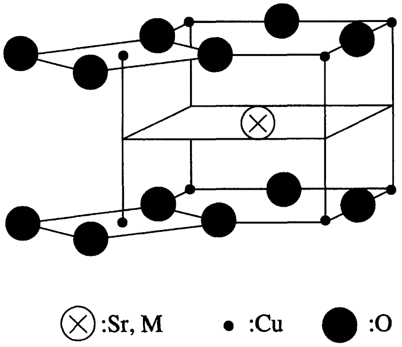

FIG. 8. The crystal structure of the infinite-layered cuprate $Sr_{1-x}M_xCuO_2$ (M = Ca, La, Nd, Pr, or vacancies).

derstanding and application of HTSy because of the following features.

1.1.2.1 Insulating Parents. Without exception, all HTSrs can be derived from their respective insulating parent compounds, through either hole or electron doping over a narrow doping range. The parent compound is an insulator when doping is below this narrow doping range and becomes a nonsuperconducting metal above. T_c depends sensitively on doping, which, in turn, is sensitive to the valence and ionic size of the dopant element, and on the synthesis conditions.

1.1.2.2 Mixed Valence and CuO_2 Layers. All HTSrs except fullerites contain elements in a mixed valence state, i.e., Cu in the cuprates and Bi in the bismuthates, and all cuprate HTSrs possess CuO_2 layers. Unfortunately, none of these common characteristics has been demonstrated to be sufficient for the existence of HTSy. More subtle factors must determine how HTSy occurs.

1.1.2.3 Strong Anisotropy. In contrast to most LTSrs, cuprate HTSrs are highly anisotropic electrically and magnetically, because of their layered crystal structure. To be more specific, electric current in both the normal and superconducting states flows more easily along the CuO_2 layers than perpendicular to these layers. The resistivity ratio between these two directions reaches $\sim 10^5$ for the case of Bi-2212 slightly above its T_c. A critical current density (J_c) ratio as high as $\sim 10^3$ has been obtained between these two directions.

1.1.2.4 High H_{c2}, Short ξ, Low Carrier Density, and Long λ (see Sec. 1.2 for definitions). HTSrs usually have a high upper critical field H_{c2}, e.g., >100 T for Y123 at 0 K and a low carrier density of ~(2 to 5) $\times 10^{21}$ cm^{-3}. As a result, the coherence length ξ is very short, ~17 and ~3 Å in and perpendicular to the CuO_2 plane, respectively; and the penetration depth λ is rather large, ~2 000 and ~10 000 Å, respectively. HTSrs are therefore extreme type-II superconductors with a Ginzburg–Landau parameter $\kappa \sim 100$.

1.1.2.5 Large Thermal-Fluctuation Effects. Because of the high T_c, short ξ, and layered structure of a HTSr, microdomains in a HTSr can fluctuate between their normal and superconducting states over a wide and easily detectable T region both above and below its T_c. This leads to an easily detectable complex magnetic-phase diagram for HTSrs, reduced magnetic flux pinning, and, hence, reduced J_c at high temperatures. For instance, J_c is almost zero at 77 K for Bi-2223 single crystals, in spite of their relatively high T_c of ~120 K.

1.2 Ginzburg–Landau Phenomenological Theory

The Ginzburg–Landau phenomenological theory (de Gennes, 1966) links the electrodynamic with the thermodynamic properties of a superconductor. In 1950, Ginzburg and Landau introduced a macroscopic quantum wave function $\Psi(r)$ with amplitude and phase to embody the quantum-mechanical nature of the superconducting state. The density of the superconducting electrons is proportional to $|\Psi(r)|^2$. Following the Landau theory of second-order phase transition, Ginzburg and Landau intuitively expressed the Gibbs free energy in a power series of $\Psi(r)$ and $\nabla\Psi(r)$ at temperatures close to T_c. They minimized the Gibbs free energy and obtained two intercoupled equations to describe an equilibrium superconducting system in the presence of a magnetic field.

The theory also provides many valuable estimates, such as the maximum critical current density (known as the depairing critical current density) when the kinetic energy of the carriers is equal to the superconducting condensation energy, $J_d = \Phi_0/12\sqrt{3}\pi^2\lambda^2\xi$, and the upper critical field $H_{c2} = \Phi_0/8\pi^2\xi^2$. In these relations, Φ_0 is a flux quantum that equals $h/2e \sim 2.07 \times 10^{-15}$ T m^2, where h is the Planck constant, e the electron charge, λ

the magnetic penetration depth, and ξ the coherence length. λ measures the extent that a magnetic field can penetrate into a superconductor, and ξ is roughly the distance between two electrons in a superconducting pair. The Ginzburg–Landau parameter also predicts a temperature-independent quantity $\kappa = \lambda/\xi$, called the Ginzburg–Landau parameter, which differentiates a type-I superconductor with $\kappa < 1/\sqrt{2}$ from a type-II superconductor with $\kappa > 1/\sqrt{2}$. A type-I superconductor is one that exhibits the Meissner effect; i.e., it completely expels magnetic flux, i.e., $B = 0$, until it becomes completely normal when the applied magnetic field (H) exceeds a critical value of H_c. Similar to a type-I superconductor, a type-II superconductor completely expels the magnetic flux but only when H is smaller than the lower critical field H_{c1}. However, the magnetic field starts to penetrate into a type-II superconductor when it is greater than H_{c1} until it reaches an upper critical field H_{c2}, beyond which superconductivity is completely destroyed (Fig. 9). The basic superconducting phenomena of HTSrs are similar to those of LTSrs and therefore have been accounted for quite well by the Ginzburg–Landau phenomenological theory.

1.3 BCS Theory

The Ginzburg–Landau phenomenological macroscopic theory can describe superconducting phenomena, but it cannot explain why and how they occur. Fröhlich (1950) predicted that lattice vibrations, known as phonons in their quantum form, can give rise to an effective attraction between the otherwise repulsive electrons and thus are important to superconductivity. Cooper (1956) showed that, in the presence of an attractive interaction, two electrons will form a bound state or a "Cooper pair" having a lower energy state, no matter how weak the interaction is. With these and other observations, together with the appropriate mathematical tools, the time was ripe in 1957 for Bardeen, Cooper, and Schrieffer to develop the first comprehensive microscopic theory of superconductivity (Bardeen *et al.*, 1957). Known as the BCS theory, it provided the first microscopic description of the origin of superconductivity. Later it was shown that the previous macroscopic theories can be derived from this microscopic theory. The three architects of the BCS theory were awarded the Nobel prize in physics in 1972. (See SUPERCONDUCTIVITY, LOW-TEMPERATURE, for details.)

According to the BCS theory, the ground state consists of Cooper pairs of electrons near the Fermi surface. It gives a superconducting transition temperature

$$T_c = 1.14\Theta_D \exp[-1/N(E_F)V],$$

where Θ_D is the Debye temperature, $N(E_F)$ the electron density of states at the Fermi energy (E_F), and V the strength of the attractive electron–phonon interaction. The BCS theory provides expressions for a wide range of properties of a superconductor, including the isotope effect, the penetration depth, and the energy gap (which is the minimum amount of energy required to split a Cooper

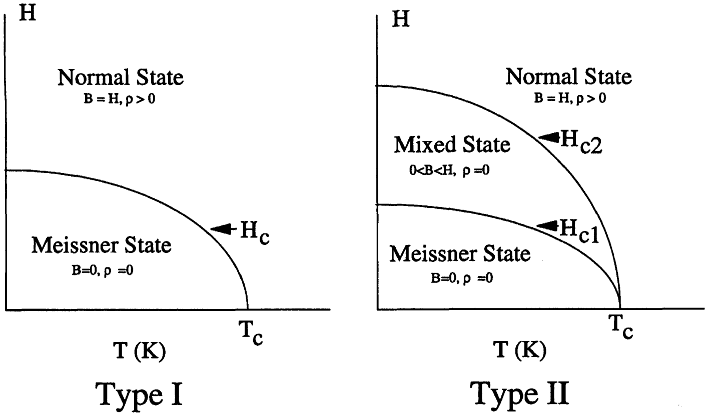

FIG. 9. Dependence of critical magnetic fields on temperature for type-I and type-II superconductors: in the Meissner state, $B = 0$ and $\rho = 0$; in the mixed state, $0 < B < H$ and $\rho = 0$; and in the normal state, $B = H$ and $\rho > 0$.

pair). The theory also accounts for many other superconducting characteristics such as tunneling, thermal conductivity, and flux quantization. Deviations from BCS predictions have been detected in LTSrs and explained over the years by modified models, which are still primarily based on the BCS theory. However, it remains an open question if BCS in its original or modified form can explain all properties of a HTSr and if an attractive electron–phonon interaction can give rise to the high T_c observed (see Sec. 4 for HTSy theoretical models).

2. SYNTHESIS

Compounds demonstrating the HTSg properties can be easily prepared in any laboratory with a mortar and pestle and a simple furnace. Perhaps this is why HTSy is the only Nobel-prize winning experiment that was quickly duplicated in high school laboratories. However, the synthesis of HTSg compounds with superconducting properties good enough for scientific and applied studies requires great effort. The complex chemistry, the anisotropic structure, and the short coherence length of the cuprate HTSrs complicate the preparation of high-quality materials. The general synthesis conditions for some representative HTSg compounds are listed in Table 1.

2.1 Polycrystalline Materials

2.1.2 Solid-State Reaction Solid-state reaction (Yan *et al.*, 1988), the simplest technique, can produce high-quality polycrystalline HTSrs. It consists of three basic steps:

1. mixing reactants in the appropriate cation stoichiometry to obtain a homogeneous precursor,
2. calcination (or reaction) of the precursor to obtain the HTSg compound, and
3. heat treatment to optimize the HTSg properties.

The reactants usually are constituent oxide, carbonate, or nitrate powders. To avoid possible residual carbon, which usually degrades the superconducting properties, oxides or nitrates are the better choice. Homogeneous polycrystalline HTSg samples can be pre-

pared by thorough mixing and calcination, followed by repeated pulverization, compaction, and sintering. However, the solid-state reaction route is tedious and time consuming, and it risks contamination due to repeated grinding and pulverization.

2.1.3 Solution-Chemistry Route The solution-chemistry route (Yan *et al.*, 1988) offers a good way to mix the reactants at the molecular level in solution and provides good control of chemical homogeneity, stoichiometry, and particle size and morphology. The techniques usually start with a mixed solution of salts of the metal elements and produce the particles by precipitation or by solvent removal. The precipitated particles need further calcination to form the HTSg compound. The techniques can be grouped into three general categories: co-precipitation, sol-gel, and spray drying. In co-precipitation, the cations are precipitated simultaneously from solution. The sol-gel method involves the formation of ultrafine particles dispersed in a solvent that is slowly evaporated resulting in excellent homogeneity control. Spray drying involves the formation of small spherical droplets of the solution with an atomizer and drying them by spraying them either into liquid nitrogen or onto a hot surface.

2.2 Textured Bulk Materials

For applications, such as electrodes, electromechanical devices, and trapped-field magnets (see Sec. 5.6), it is essential to raise the critical current density (J_c) of the polycrystalline samples produced by the above techniques. Because of their large structural and electrical anisotropy and their complex chemistry, HTSrs are prone to formation of weak links, resulting from the presence of high-angle grain boundaries, microcracks, off-stoichiometric regions, chemical inhomogeneity, and impurity phases. These Josephson-coupled (see Sec. 5.2) weak links restrict J_c: The J_c of a polycrystalline HTSr is low and decreases rapidly with magnetic field.

Cuprates usually decompose to a mixture of solid and liquid phases above a temperature known as the peritectic decomposition temperature (T_p), which is typically 1320 K. The melt-texturing process (Murakami *et al.*, 1989; Salama *et al.*, 1989) was developed to reduce the number of weak links in cuprates. This process involves heating a HTSr rapidly to above T_p followed by slow cooling to below T_p. After melt texturing, Y123 grains are formed with their CuO_2 planes preferentially aligned. At 77 K, J_c's up to $\sim 8 \times 10^4$ A/cm^2 and $\sim 2 \times 10^3$ A/cm^2 have been achieved in melt-textured Y123 at zero and 30 T, respectively. Unfortunately, the grains so obtained are small. Melt-textured BSCCO, TBCCO, and HBCCO have not yet been achieved.

To enhance the grain size in a large sample of RBCO, one may adopt the directional solidification technique (Meng *et al.*, 1990), which requires that during melt texturing one maintains a temperature gradient, a compositional gradient of R, and/or a stack of thin layers of RBCO with different R's across the bulk precursor in the c-axis direction intended during melt texturing. Samples exhibiting a large J_c with a length of a few centimeters but only a small cross-sectional area of ~ 0.2 cm^2 have been obtained.

A "top-seeding technique" (Sawano *et al.*, 1991) can control the crystal nucleation and growth during melt texturing: It is essential for obtaining large quasi single-grain HTSrs. The technique involves introducing a small single-grain HTSr as a seed to the top of the HTSr precursor, with or without a temperature gradient, before melt texturing. The seed must have a melting or decomposition point above T_p of the specific HTSr disk processed. HTSr disks of 3 cm diam. × 1 cm thick have been obtained (Plate 1), to trap a field of 1.5 T at 77 K and 6 T at 40 K and to shield a field greater than 21 T at 4.2 K (Gao *et al.*, 1994b).

2.3 Wires and Ribbons

For many large-current applications, such as generators, motors, power-transmission lines, and high-field magnets, the most practical forms of HTSrs are wire and ribbon. For several applications, the requirements on J_c, the total critical current (i.e., $J_c \times$ cross section), and length of the HTSg wires and ribbons are shown in Fig. 10. Since HTSg materials are mechanically brittle and electrically anisotropic, the fabrication of HTSg wires or ribbons with large J_c and great length is a formidable task. The powder-in-tube (PIT) method (Sato *et al.*, 1991) has

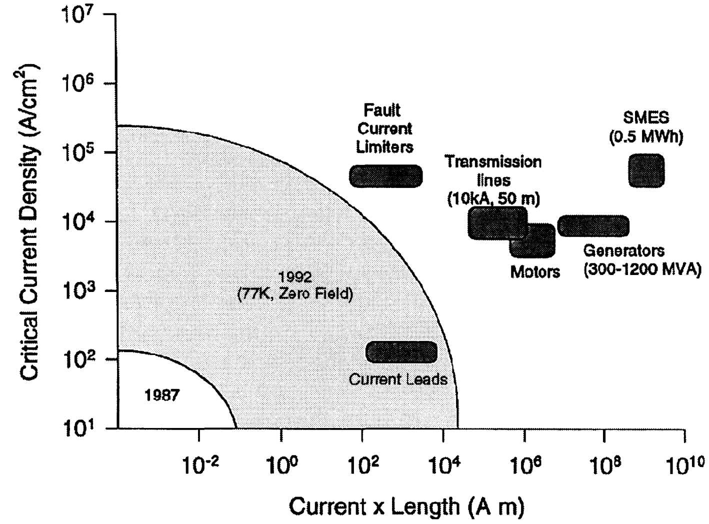

FIG. 10. The conductor characteristics required for various commercial applications. The shaded area represents the developments between 1987 and 1992, and SMES means superconducting magnetic-energy storage (Electric Power Research Institute Report, 1992).

yielded short BSCCO ribbons that display large $J_c \sim 10^5$ A/cm^2 at 4.2 K, even at fields higher than 20 T. BSCCO ribbons of length of more than 1 km have been prepared by American Superconductor Corporation in the United States and Sumitomo in Japan with an overall J_c of better than 8×10^3 A/cm^2 at 77 K. Very recently, American Superconductor Corporation made BSCCO multifilament wire over 1 km long with a $J_c \sim 14 \times 10^3$ A/cm^2 at 77 K. The PIT method involves filling a metal tube with powder of the HTSg compound, drawing the filled tube to wire of smaller diameter, and rolling the wire to ribbon, followed by repeated compression and heat treatment (Fig. 11). A multifilament wire can be made by bundling together the HTSg wire made by the PIT method through a multistage process. The starting HTSg material is ground into fine particles of uniform size. Pb dopant in BSCCO facilitates the formation of the pure Bi-2223 phase, which shows the best J_c of the BSCCO-homologous series. Repeated drawings not only reduce the diameter of the HTSg wire but also enhance the packing density of HTSg powder inside the tube for better texturing in subsequent processing. The rolling step further reduces the overall thickness of the HTSg component inside the ribbon and, more importantly, induces partial grain alignment with the c axis perpendicular to the ribbon

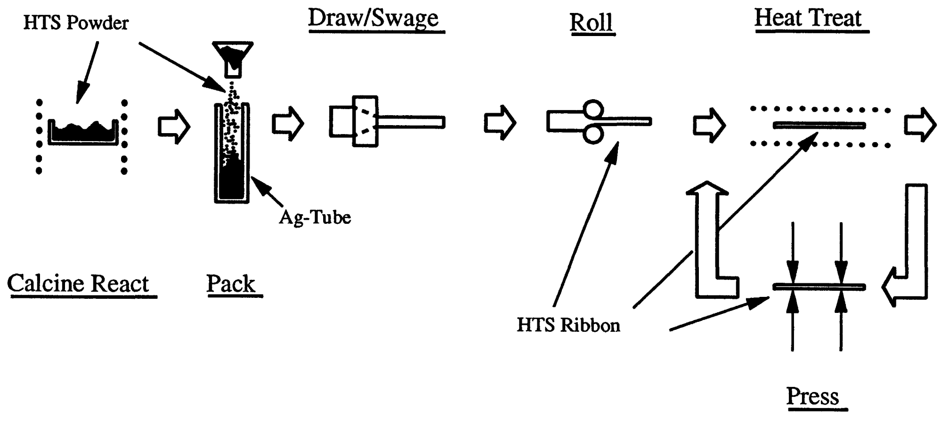

FIG. 11. The powder-in-tube technique for the production of HTS ribbons.

surface. The final compression is also important for grain alignment. A representative set of parameters and conditions for processing silver-sheated BSCCO is given in Table 2.

The cladding metal used should not melt or react with the HTSg material at the processing temperature. At the same time, it must be permeable to oxygen. Silver, palladium-doped silver, and gold are the only suitable choices for BSCCO ribbons.

The major problem with BSCCO wire is the drastic drop of its J_c at 77 K resulting from motion of the flux lines under the influence of current due to the weak flux-pinning force. Flux pinning at 77 K is much stronger in Y123, Tl-1223, and HBCCO. For Y123, the PIT method fails: because of the strong coupling between the CuO_2 layers in Y123, it cracks during rolling, rather than flowing as BSCCO does. The chemical instability of HBCCO at temperatures close to the ribbon processing temperature poses a serious challenge to ribbon making. Promising preliminary results have recently been reported for Tl-1223 thick films on a short Ag ribbon with a J_c up to ~6.7 × 10^4 A/cm^2 at 77 K by the National Renewable Energy Laboratory, General Electric, and Oak Ridge National Laboratory; and for Y123 thick films on a short flexible Ni strip with a J_c of ~1 × 10^6 A/cm^2 at 75 K by the Los Alamos National Laboratory. The Tl-1223 ribbon was made by properly heating the atomic-size precursor oxides deposited electrochemically on the Ag substrate. The Y123 thick film on the Ni strip was prepared by the laser ablation technique, to be described in Sec. 2.5.3, using a buffer layer with a good crystalline alignment.

2.4 Single Crystals

Large single crystals are best for determining the intrinsic physical properties of a material. The growth of large HTSg single crystals is difficult because the material melts incongruently; i.e., the concentration of the intended HTSr is different from that of the melt. Additional problems include the corrosive nature of the melt, which makes it difficult to find an inert crucible material, and the lack of detailed knowledge of the phase diagram. Relatively large 214-HTSg single crystals of high quality have been obtained. Crystals of Y123 (up to ~10 × 9 × 9

Table 2. Power-in-tube BSCCO-wire processing parameters.

Compound	Composition					Precalcination (°C)	Atmosphere	Wire Treatment (°C)	Time (h)	J_c (10^4 A/cm^2)	
	Bi	Pb	Sr	Ca	Cu					4.2 K	77 K
Bi-2223(*a*)	1.6–1.9	0.32–0.4	1.9–0.4	2.0–2.2	3.0–3.1	800–830	Air or ~8% O_2	820–840	100–200	20	5.4

mm^3) and thin BSCCO and TBCCO crystals (~0.5 mm thick) are also available with an acceptable quality for detailed studies. However, few single crystals of practical size of other compound systems exist. Large, contamination-free, high-quality single crystals of materials other than 214 suitable for detailed neutron-spectroscopy studies have yet to be synthesized.

Various growth techniques for producing high-T_c crystals have been tested and yield some results (Schneemeyer, 1993). The common-flux technique has been used to grow single crystals from two possible types of HTSr saturated solution: one solution consisting of a flux of one component of the HTSg compound such as CuO or $BaCuO_2$ in the R123 or 214 compounds and the other an inorganic salt such as KCl or KOH. Single crystals of the R123 or 214 compound have been grown by slowly cooling the saturated solution inside a crucible (Al_2O_3, Zr_2O_3, Au, Pt, or Ag/Pd). Although the method is simple, it suffers from crucible contamination. The best crucible materials appear to be Au, Ag/Pd, and Zr_2O_3 alloy in terms of chemical stability, and Pt in terms of resistance to thermal shock.

Recently, a continuous pulling method has been developed to grow single crystals of Y123 from a solute-rich liquid. Y211 powder is first introduced as a solute at the bottom of a crucible that is made of Y_2O_3 or MgO. A constant temperature gradient of several degrees higher at the bottom of the crucible is maintained, while the surface of the solvent, melted oxides of Ba and Cu, is kept at ~1000 °C. The seed crystals used are single-crystal MgO with appropriate surface treatment. High-quality Y123 crystals with large facets ~10 mm along the *c* axis and 9×9 mm^2 along the *a-b* plane have been grown.

2.5 Thin Films

HTSg thin films are essential for many applications that involve small currents, such as microelectronics and ultrasensitive sensors. They are also crucial for fundamental studies such as tunneling spectroscopy, proximity effect, anisotropy effect, grain-boundary effect, and flux pinning. High-quality thin films must possess the correct stoichiometry, the correct crystal structure with a proper orientation, chemical homogeneity, uniform thickness, smooth surface morphology, proper microstructure, and no impurity phase. Epitaxially grown films that satisfy the above criteria display excellent superconducting properties, e.g., high T_c, narrow transition width, high J_c, low surface impedance (R_s) at high and low frequencies, and high chemical stability. Excellent Y123 and TBCCO thin films of a couple of thousand angstroms thick have been prepared with a $J_c \sim (3 \text{ to } 5) \times 10^6$ A/cm² at 77 K. Multilayered structures with up to 15 epitaxial layers consisting of Y123 with buffer layers and insulators have been fabricated by Conductus in California. High-quality BSCCO films have been made by Varian in California.

Careful consideration must be given to the selection of substrate materials. Lattice match, thermal compatibility, absence of HTSr/substrate interdiffusion, and, for high-frequency applications, low dielectric constant and low loss tangent are all issues to consider. Common substrate materials include $LaAlO_3$, MgO, $SrTiO_3$, Sr_2AlNbO_6, Sr_2AlTaO_6, and sapphire.

2.5.1 Evaporation The starting source materials, which can be elements and/or compounds, are thermally evaporated (Mankiewich *et al.*, 1987) from a crucible by resistive heating or by an electron beam. The atomic or molecular species of the material move freely toward the substrate located near the source, resulting in epitaxial deposition of the HTSg material on the substrate. The properties of the thin film are influenced by the substrate temperature, deposition rate, oxygen partial pressure, and the source-to-substrate distance. Often, films require post-annealing in an oxygen atmosphere *in situ* after deposition to acquire the proper oxygen content. Plasma- and ion-assisted coevaporation improve the oxygen content and yield superconducting films without post-annealing.

2.5.2 Sputtering Sputtering (*q.v.*) is a common thin-film deposition technique (Eom *et al.*, 1989). The dc-diode sputtering method (Fig. 12) illustrates the basic principle. When a dc voltage of 1–2 kV is applied between the cathode (the target) and the anode (the substrate) in a low-pressure gas environment, a discharge is generated. The positive ions in the discharge accelerate toward the target and impinge on it at high

speed. They eject molecules from the surface of the target. These ejected molecules then deposit on a heated substrate to form a thin film. Single or multiple targets containing the appropriate components have been used to synthesize HTSg thin films. The target can be a compound or mixed powder, and the sputtering atmosphere can be argon, oxygen, or argon/oxygen mixed gas at different pressures. For an insulating target, e.g., one made of prereacted metal oxide powders, the dc sputtering technique fails, and so an rf source is used.

2.5.3 Laser Ablation Laser ablation (Inam *et al.*, 1988) is the simplest and most versatile method for preparing high-quality HTSg thin films, which are epitaxial and sometimes even single crystalline. A high-power laser system, e.g., a 50-W ArF excimer pulsed laser (~50 Hz) at 193 nm wavelength, is used. The laser beam strikes the HTSr target, generating a plume that consists of an active plasma and radical atoms. The particles ablated from the target are deposited at the heated substrate (Fig. 13). The kinetic energy (1–40 eV) and the internal excitation energy (a few electron volts) of these particles facilitate their rearrangement after they reach the substrate, resulting in a good growth of the HTSg thin film. The process requires no bias voltage and is operable in any atmosphere at any pressure. The film stoichiometry is the same as the target composition. The superconducting films are easily made *in situ* without post-annealing.

2.5.4 Molecular-Beam Epitaxy The layered structure of HTSrs enables one to fabricate HTSg films by condensing layer by layer of the metal-element vapors in a low-pressure oxidizing atmosphere. The complete deposition of each layer is evidenced by the appearance of an intensity peak in the reflection high-energy electron-diffraction pattern (Kawai *et al.*, 1988). The starting metal-element vapors can be generated by laser ablation or by heating the sources in well-controlled cells. The method has been

demonstrated to be very effective in producing metastable compounds, such as the $n \geq 4$ members of the homologous series of BSCCO, which are difficult to form using the other methods described above.

3. EXPERIMENTAL PROPERTIES

Since 1987, nearly all experimental tools available for the characterization of solids have been applied directly or with modifications to the studies of HTSrs. With the rapid progress in controlling the sample quality, properties of well-characterized HTSrs are now available. In this section, the transport and magnetic properties, which have a direct bearing on both the understanding and applications of HTSy, are discussed.

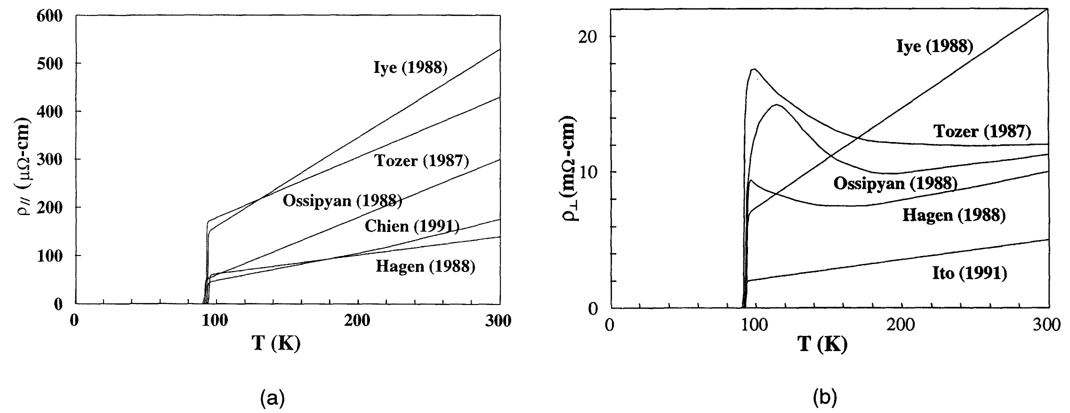
3.1 Transport Properties

3.1.1 Normal-State Resistivity The normal-state resistivity (ρ) of the cuprate HTSrs is highly anisotropic, reflecting the layered crystal structure. The resistivity in the CuO_2 planes ($\rho_{\parallel}$) at room temperature is $\sim 3 \times 10^{-4}\ \Omega$ cm, but the resistivity perpendicular to the planes ($\rho_{\perp}$) is much higher. The anisotropy ratio of ρ ($\rho_{\perp}/\rho_{\parallel}$) of Y123 is nearly 100. In Bi-2212, an anisotropy ratio on the order of 10^5 was observed (Martin *et al.*, 1988).

For compounds optimally doped for highest T_c, $\rho_{\parallel}$ varies linearly with the temperature (T) (Iye, 1992) [Fig. 14(a)]. The linear T behavior can extend over a wide range, from T_c up to the decomposition temperature of the material. In the case of Bi-2201, the range represents two orders of magnitude in temperature, from 6 to 600 K. In $La_{1.85}Sr_{0.15}CuO_4$ the linear T behavior of ρ in the CuO_2 plane continues to temperatures above 1000 K. Unlike normal metals, the $\rho_{\parallel}$ of these optimally doped compounds does not saturate at high temperatures nor flatten out for temperatures below the Debye temperature. The T dependence of $\rho_{\perp}$ remains controversial: both hopping and metallic behaviors have been observed [Fig. 14(b)]. The hopping behavior may result from oxygen deficiency. For compounds not optimally doped and for the electron-doped $Nd_{2-x}Ce_xCuO_{4-\delta}$ compounds, a T^2 term enters $\rho_{\parallel}$ prominently at low temperatures, before hopping or localization sets in.

3.1.2 Critical Current Density The critical current density (J_c) is ultimately limited by the depairing current density (J_d) (see Sec. 1.2). At 0 K, $J_d \sim 3 \times 10^8$ A/cm^2, similar to that for LTSrs. Above 0 K, thermal excitations come into play and suppress J_c to $\sim 10^7$ A/cm^2 at 77 K. This is the actual limit only if fluxoids are completely pinned.

Under the influence of a Lorentz force, the fluxoids inside a superconductor will move, resulting in a loss when the Lorentz force is greater than the pinning force $\propto \xi^2$. Defects of sizes $\leq \xi$ introduced by irradiation or by processing steps are required to act as pinning centers to enhance J_c. Some of the best representative results are summarized in



(a) (b)

Fig. 15, where Nb_3Sn, the best LTSr, is included for comparison. HTSrs clearly outperform LTSrs at high field. The J_c in thin films has approached the theoretical value set by the depairing limit.

3.1.3 Surface Impedance The surface impedance (R_s) below T_c measured at microwave frequencies (ν's) determines the energy loss of a HTSr and is a measure of its suitability for microwave devices. The penetration depth λ, the weak links present, and the magnetic flux trapped within a distance λ from the surface are the important parameters in determining the magnitude of R_s. For a BCS superconductor at low temperatures, the dependence of R_s on T and ν is $(\nu^2/T) \times \exp(-\Delta_0/kT)$, where Δ_0 is the energy gap at 0 K. For HTSrs, a deviation is expected because of the linear-T behavior of the normal-state resistivity ρ, the T-dependent motion of trapped flux, and the T dependence of the ever-present weak-link effect. Representative data points for R_s at 77 K and different ν's are displayed for Y123 in Fig. 16, which also shows the $R_s(\nu)$ dependence of superconducting Nb at 7.7 K and Cu at 77 K for comparison.

3.1.4 Hall Effect above T_c The normal-state Hall coefficient (R_H) of the HTSg materials (Ong, 1992) has positive sign for the hole-doped compounds and negative sign for the electron-doped Nd(Ce)-214. The R_H of the HTSg materials is, in general, strongly dependent on T, obscuring any simple interpretation as a measure of the charge-carrier density. The T dependence of R_H in many HTSg materials above T_c can be fitted by $(\alpha + T)/(\beta + T^2)$, where α and β are material-dependent parameters proportional to the density of crystal defects. In the case of pure Y123, α and β are close to zero, giving an R_H proportional to T^{-1} or a Hall number p_H proportional to T. p_H is defined as V/eR_H, where e is the electron charge and V is the unit cell volume. As the doping is reduced, this T dependence of p_H persists until the compound is no longer superconducting (Fig. 17).

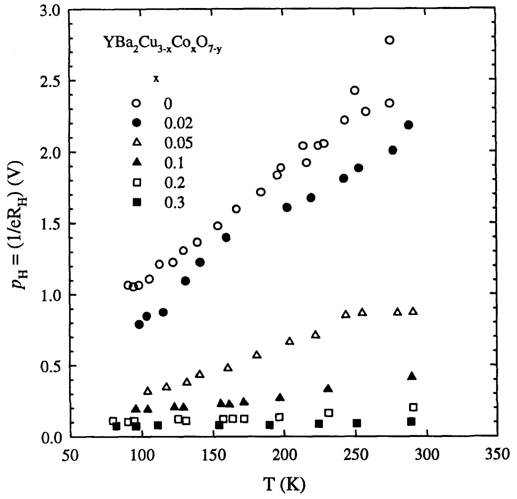

FIG. 17. The temperature dependence of the Hall number p_H for Co-doped Y123 (Clayhold *et al.*, 1989).

3.1.5 Thermal Conductivity

3.1.5 Thermal Conductivity The thermal conductivity of Y123 is almost T independent between room temperature and T_c and drops rapidly after an upturn below T_c (Uher, 1992). In single-crystal material, along the a-b plane, the thermal conductivity above T_c is κ_{ab} = 12.5 W/K m, and in the c direction it is smaller, κ_c = 0.4 W/K m; both are a few hundred to a thousand times smaller than that of Cu. Comparison with the Wiedemann–Franz law indicates that approximately 50% of the in-plane thermal conductivity is due to the charge carriers. In contrast, nearly all the c-axis heat conduction is due to phonons. The thermal conductivity of ceramic material depends upon its processing history (Fig. 18) but is often lower by a factor of 2–5 than the single-crystal values of κ_{ab}.

3.1.6 Thermoelectric Power Above T_c, the thermoelectric power (TEP) decreases almost linearly with increasing T for most hole-doped HTSrs and does not show any sign of phonon drag [Fig. 19(a)]. The underlying mechanism for such a T dependence is not yet known. However, a systematic trend of TEP variation with doping and a universal correspondence of the room-temperature TEP with the carrier per CuO_2 layer (p) was uncovered [Fig. 19(b)] (Obertelli *et al.*, 1992). The room-temperature TEP varies linearly with p for the overdoped HTSrs and exponentially for the underdoped ones, and thus provides a simple qualitative method for the characterization of HTSg materials. A quadratic T_c-p relation was also obtained to describe many of the HTSg systems [Fig. 19(c)] (Presland *et al.*, 1991).

3.2 Magnetic Properties

Extensive efforts have been directed toward the investigation of the flux dynamics of HTSrs. Although complete descriptions of

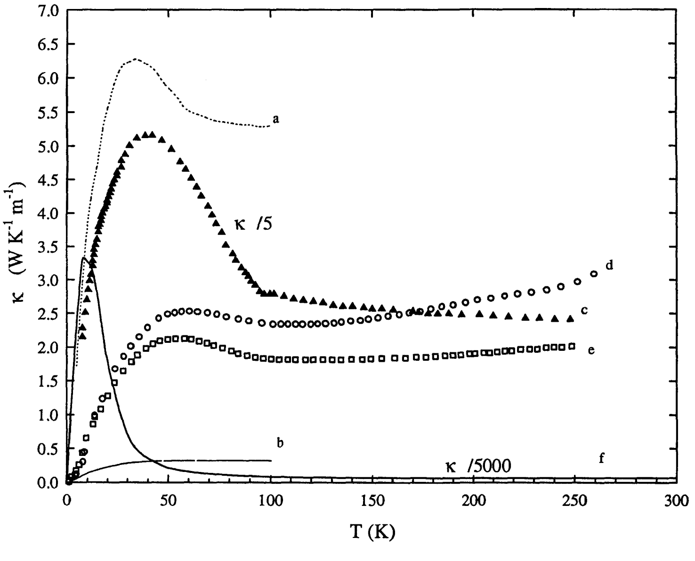

FIG. 18. The temperature dependence of the thermal conductivity of Y123: curve *a*, single crystal in the *a–b* plane; curve *b*, single crystal in the *c* direction; curve *c*, high-quality single crystal in the *a–b* plane; curve *d*, hot-pressed polycrystalline sample in the direction perpendicular to the direction of hot pressing; curve *e*, polycrystalline sample in the direction parallel to the direction of hot pressing. the magnetic properties of HTSrs in the superconducting state have yet to be developed, insight has been gained into the movement of fluxoids (Huse *et al.*, 1992).

For $H_{c1} < H < H_{c2}$, a type-II superconductor is said to be in the mixed state (Fig. 9), where ρ remains asymptotically small as H enters the interior of the superconductor discretely in the form of fluxoids or flux quanta. Each flux quantum has a supercurrent circulating over a range λ around its normal core (of size $\sim\xi$). In a defect-free type-II superconductor, the fluxoids form a rigid flux lattice, which will move in the presence of an externally applied current in response to the Lorentz force (Fig. 20). The movement of these fluxoids through the sample produces an electric field opposite to the current flow and thus leads to energy dissipation.

The introduction of defects of a dimension $\sim\xi$ to a superconductor will destroy the periodicity of the flux lattice. The fluxoids may cluster and be pinned around the defects. These flux bundles may or may not move, depending on the balance between the flux-pinning force (associated with defects and interfluxoid interaction) and the depinning force (due to the Lorentz force and thermal activation).

The mixed state was generally considered a featureless phase region until the discovery of HTSrs. HTSrs are type-II superconductors. Their high T_c, short ξ, low carrier con-

centration (n), and large λ greatly enlarge the area under the critical-field line in the H-T phase diagram. The larger range of the parameter space enhances the likelihood of detecting any possible differences within the mixed state arising from the different detailed balances among the various forces acting on and between fluxoids. Indeed, an additional boundary (Fig. 21) has been observed (Brandt, 1991), i.e., the irreversibility line $H_i(T)$ [or $T_i(H)$] below $H_{c2}(T)$. Above $H_i(T)$, the response of a HTSr to an H change is reversible, i.e., the vortices behave as a fluid; below it, the response is irreversible. $H_i(T)$ can be treated operationally as a boundary below which the dissipation drops so rapidly that an upper bound of J_c can be defined. The nature of $H_i(T)$ is rather complex and depends on a combination of characteristics such as interlayer coupling, flux-pinning strength, and the defect morphology. As a result, a convergent interpretation of $H_i(T)$ is still lacking. Interpretations range from a first-order melting through a second-order vortex-glass transition to a Bose-glass transition. Additional features in the H-T phase diagram have also been reported, and their origins are unknown.

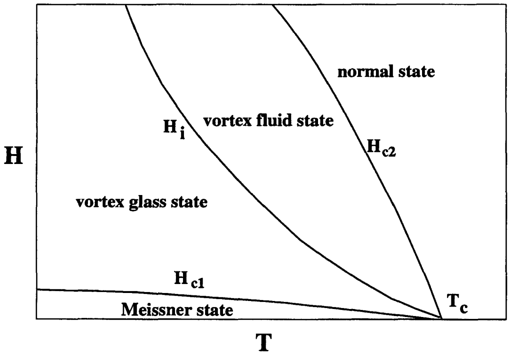

FIG. 21. The schematic H-T phase diagram for a HTSr: $B = 0$ and $\rho = 0$ in the Meissner state; $0 < B < H$ and $\rho = 0$ in the vortex glass state; $0 < B < H$ and $\rho \neq 0$ in the vortex fluid state; and $B = H$ and $\rho \neq 0$ in the normal state.

3.3 Symmetry of the Superconducting Order Parameter

The symmetry of the superconducting order parameter refers to the angular dependence of the superconducting energy gap ($\Delta_{\mathbf{k}}$) in the reciprocal lattice (**k**) space, which is uniquely related to the crystal structure. Since superconductivity in both LTSrs and HTSrs involves the pairing of electrons (or holes) of opposite spin, the angular dependence of $\Delta_{\mathbf{k}}$ is determined by the angular momentum (l) state of the pairing electrons (or holes). For $l = 0$ (the s wave), $\Delta_{\mathbf{k}}$ never vanishes in **k** space and is known as nodeless. It has the same symmetry as the crystal and therefore can be isotropic (same in all directions) or anisotropic (different values in different directions) in the **k** space. However, for $l = 2$ (d-wave pairing), $\Delta_{\mathbf{k}}$ vanishes at points or lines in certain directions of **k** and so is said to have nodes or node lines and needs not display the same symmetry as the crystal. The existence of nodes or node lines in $\Delta_{\mathbf{k}}$ enables a very small amount of energy to excite the electrons of a superconductor in its superconducting state. As a result, several distinct signatures in both the microscopic properties and macroscopic behavior are predicted for a d-wave superconductor (Annett *et al.*, 1989). Knowledge of the symmetry of $\Delta_{\mathbf{k}}$ has been thought by some to hold keys to the HTSr mechanism mystery.

No nodes or node lines have been detected in the conventional LTSrs, and so their $\Delta_{\mathbf{k}}$ has the s symmetry. However, d pairing is evidently present in a small but interesting class of LTSrs known as heavy-fermion superconductors such as UPt_3 and UBe_{13} (see HEAVY-FERMION PHENOMENA).

The situation in HTSrs remains controversial (Levi, 1993; Schrieffer, 1994) in spite of the many sophisticated experiments done on Y123 and Bi-1212. For instance, a linear T dependence of λ suggesting a d pairing in Y123 has been reported by some experiments in contrast to a quadratic T dependence, consistent with an s pairing, by others. Also considered are the results of tunneling experiments. Josephson pair tunneling between Y123 and Pb (a conventional LTSr) observed along the c axis of Y123 is consistent with an s pairing (Sun *et al.*, 1994). In contrast, in a so-called corner dc SQUID, which consists of a pair of Y123/Au/Pb tunnel junctions along the a and b axes of a Y123 single crystal, a critical-current dip in zero external field was observed, which is compatible with a d pairing (Wohlman *et al.*, 1993). Very recently, an elegant experiment was carried out (Tsuei *et al.*, 1994) by measuring the spontaneous magnetization of tricrystal superconducting rings of Y123 with various orientations of the substrate crystals. With proper orientations between the crystals, which determine the relative orientation of the order parameters with respect to the junction interface, a spontaneous magnetization of a half magnetic flux quantum has been unambiguously discovered, in agreement with a d-wave pairing symmetry. Angular resolved photoemission results (Shen *et al.*, 1993) showed the existence of lines of nodes in $\Delta_{\mathbf{k}}$ along the direction predicted by the theory. However, another set of results obtained by a different group (Gofron *et al.*, 1994) suggested an anisotropic s wave.

The above inconsistencies have been ascribed to possible different sample qualities, different junction conditions, a combination of s and d wave, or a highly anisotropic s wave. Adding to the uncertainties is the recent suggestion (Abrikosov, 1995) that some of the above tunneling results indicative of d-wave pairing may be associated with the orthorhombic structure symmetry of Y123. A tunneling experiment similar to that of Tsuei *et al.* (1994) using the tetragonal HTSr will resolve this uncertainty.

4. THEORETICAL STATUS

The Ginzburg–Landau theory satisfactorily describes the general superconducting phenomena of HTSrs on a macroscopic level without explaining the occurrence of HTSy or the mechanism responsible for it. On the microscopic level, many models have been proposed to explain HTSy. Some fall into the framework of the BCS theory while others do not. They may be combined into three groups, based on the origin of the interaction. Most of them are built on the assumption that HTSy occurs in a two-dimensional electron system, namely, the CuO_2 layers, although the exact dimensionality of the HTSy observed is still not known.

4.1 Magnetic Models

Immediately after the discovery of HTSy, Anderson (1987) pointed out that the copper-oxide layers are the key building blocks in these compounds. He proposed the large-positive-U Hubbard model to describe the HTSrs. In this model, the electrons move in a square lattice with a repulsive interaction (U) between them at each of the lattice sites. Subsequent discoveries of the long-range antiferromagnetic (AF) order and other magnetic properties in the insulating La_2CuO_4 turn out to be consistent with the low-temperature behavior of the Hubbard model in the strong-coupling limit. The most fascinating but difficult problem is associated with the doping, which results in a transition at low temperature from the insulating AF state to the superconducting state. As discussed earlier, the normal state of these HTSrs also exhibits some remarkable nonconventional metallic behaviors. Even within the general context of the Hubbard model, different theories exist.

In the strong-coupling regime (large U), the resonant valence-bond (RVB) state (Baskaran *et al.*, 1987) and its various generalizations have later been considered as possible candidates for the solution of the Hubbard model. In the RVB state, the electrons are considered to form some exotic short-range AF ordering. Although the prediction of charge (holon) and spin (spinon) separation in the RVB theory appears consistent with some experiments (Chien *et al.*, 1991b), the RVB theory has not been fully developed because of strong interactions existing between spinons and holons. HTSy arises from interlayer coupling in this model and is therefore more three-dimensional.

In an alternative approach, Montoux and

Pines (1992) obtained expressions for the electron band structure and the spin fluctuation spectrum using photoemission and nuclear magnetic resonance data. Using these expressions, they solved the basic equations for a superconducting system, known as the Eliashberg equations, and obtained an estimate of T_c in agreement with experiment and a "d-wave" pairing symmetry. This approach can be considered less "exotic" than RVB, since the charge–spin separation is not invoked.

4.2 Electron–Phonon Interaction Models

The conventional electron–phonon coupling theory for superconductivity (Bardeen *et al.*, 1957), which has been investigated extensively for the past 30 years, is mathematically rigorous and physically sound, if Landau's Fermi-liquid theory for the charge carriers is valid and the so-called Migdal approximation holds. Landau's theory asserts that even in the presence of strong interactions, such as the Coulomb interaction, the charge carriers behave similarly to a gas of noninteracting fermions, which follow a Fermi–Dirac distribution. The Migdal approximation is a simplification made on the calculations, possible only when the phonon energy is much smaller than the electron energy. Electron–phonon coupling has not been regarded as the main mechanism for causing HTSy in cuprates, since band-structure calculations do not reproduce the AF insulating phase together with other magnetic properties in La_2CuO_4, the unusually high T_c of HTSrs, and the extremely small isotope effect in Y123.

Recently, however, evidence for a nonnegligible role of the electron–phonon interaction has emerged. This evidence includes the proposition of anharmonicity that accounts for the small isotope effect observed in certain HTSg compounds (Crespi *et al.*, 1991), and the explanation of the linearly T-dependent resistivity in terms of electron–phonon interaction, although its contribution to T_c does not seem to be dominant (Xing *et al.*, 1988). A band-theory-like Fermi surface with van Hove singularities has also been suggested (Campuzano *et al.*, 1990) by photoemission and positron-annihilation experiments. Models based on the electron–phonon interactions have been proposed (Newns *et al.*, 1992) to account for the high T_c and some anomalous properties of HTSrs by taking advantage of the large density of states associated with the van Hove singularities near the Fermi surface.

4.3 Marginal Fermi-Liquid Model

Although it is possible to argue that the linearly T-dependent resistivity is due to electron–phonon interactions, it is difficult to explain the linearly frequency-dependent Drude scattering rate in terms of electron–phonon scattering. The linearity of the scattering rate over a large frequency range ($h\nu \sim$30–300 meV) suggests that the quasiparticles are being scattered by excitations whose spectral density covers a similarly wide range in energy. This is a characteristic of the marginal Fermi-liquid (MFL) spectrum proposed phenomenologically (Varma *et al.*, 1989) to explain the linear scattering rate, as well as other observations. Within the MFL framework, one obtains a scattering rate $1/\tau \propto \max(h\nu, k_BT)$, where h is the Planck constant and k_B the Boltzmann constant, assuming that the quasiparticles interact with fluctuations that have a flat bosonic spectrum. By definition, the MFL spectrum is a phenomenological form for the dressed electron–hole polarizability. This form for the polarizability appears to be directly observable in the Raman scattering as an unusual continuum in the Raman intensity extending out to energies comparable to an interband transition (Sugai, 1989). This interpretation is controversial, as the observed continuum is surprisingly insensitive to doping and has even been detected in the insulating phase (Reznik *et al.*, 1993). The MFL theory is a phenomenological theory and, as yet, has no microscopic basis of support.

5. APPLICATIONS

A superconductor can carry a large current without loss at low frequencies and with a low loss at high frequencies, trap and shield a strong dc magnetic field, shield electromagnetic signals, display a drastic resistivity change near T_c, and exhibit novel behavior when made into tunneling junctions. Many application concepts have exploited one or more of these characteristics. Some examples are given below.

5.1 Conductors

Many large-current applications require long lengths of HTSg wire capable of carrying large electric current with negligible or minimal loss, mechanically strong and flexible enough to withstand the manufacturing process, and cryogenically stable enough to avoid thermal runaway. Groups in Japan and the United States have fabricated long powder-in-tube (PIT) wires from the BSCCO 2223 phase with high critical current densities at 77 K in their own magnetic field. Most recently, American Superconductor Corporation has reported a 1.16-km length with a J_c of 13 800 A/cm^2 (Riley, 1994).

J_c of BSCCO at 77 K decreases rapidly in the presence of an external magnetic field, but, at temperatures up to 30 K, J_c remains relatively high in strong magnetic fields. As the operating temperature is reduced, the J_c increases and becomes less field dependent. At 4.2 K, a 3-cm-long Bi-2223 wire was reported to have a $J_c \sim 2.5 \times 10^5$ A/cm^2 in 0 T, which decreases only to $\sim 1 \times 10^5$ A/cm^2 at 25 T (Haldar and Motowidlo, 1992). As the wire length increases, the achieved value of J_c decreases.

Many groups in the United States and Japan have produced BSCCO wires and tapes that are flexible enough to be wound into coils. A five-horsepower synchronous motor was recently demonstrated by Reliance Electric (Fig. 22) using the American Superconductor Corporation HTSg coils. A magnet made by Intermagnetics General Corporation, which consists of 10 pancake coils and contains a total of 480 m of HTSg tape, has generated the highest fields: 2.6 T at 4.2 K, 1.8 T at 27 K, and 0.36 T at 77 K. This magnet and a horseshoe HTSg magnet made by American Superconductor Corporation are shown in Fig. 23. Many researchers are confident that HTSg magnets will eventually generate fields in excess of 20 T at temperatures of 20 K or higher. The first application will likely be in hybrid magnets that generate strong fields by combining LTSg coils with HTSg coils.

Since the ability of BSCCO coils to generate strong fields seems intrinsically restricted to temperatures below 30 K, some groups are pursuing various approaches to making conductors from the Tl-1223 or Y123 phases and even from Hg1223, all of which have higher irreversibility lines than BSCCO (Fig. 24). In principle, Tl-1223 and Y123 and Hg1223 coils could generate high fields at 77 K, if suitable processing techniques could be developed. Short Tl-1223 wires made by the PIT technique have J_c near 10 000 A/cm^2 at 77 K (Seido *et al.*, 1992), and Tl-1223 ribbons made by electrodeposition possess J_c up to 67 000 A/cm^2 at 77 K (Seido *et al.*, 1992). An impressive $J_c \sim 2 \times 10^6$ A/cm^2 at 75 K has recently been achieved by using the laser ablation technique to deposit Y123 thick films on a Ni substrate with a textured buffer layer (Wu *et al.*, 1994). Effort on Hg-1223 wires has just been started. The chemical instability of Hg-1223 is a challenge.

5.2 Josephson Junctions and SQUIDs

The Josephson junction is the key element of superconducting electronics, based on observations that led to the awarding of the 1973 Nobel prize in physics to its discoverer, Brian Josephson. It consists of two weakly coupled superconducting regions, usually in a superconductor–insulator–superconductor (SIS) or superconductor–normal metal–superconductor (SNS) trilayered structure. Only recently have SNS junctions of cuprate HTSrs been made to display successfully Josephson tunneling with hysteretic *I-V* characteristics or two well-defined voltage states for a switching device (Fink *et al.*, 1992; Virshup *et al.*, 1992). The difficulty may be attributed to the extremely short ξ of cuprate HTSrs, comparable to the unit cell dimension. The short ξ, especially perpendicular to the CuO_2 layers, poses stringent conditions on the fabrication of the superconducting layers. Planar junctions with weak links may alleviate the problem partially by tunneling electrons into the CuO_2 layer. Other reasons associated with possible anomalous electronic properties of the HTSg cuprates cannot be ruled out.

A variety of alternative Josephson devices made of Y123 films and using a diverse set of weak links have been fabricated and have yielded reasonable results. The first devices were based on weak links that occur naturally between grain boundaries in poor-quality films. The random appearance of grain boundaries throughout the films increases noise and makes device fabrication difficult to control.

Methods were subsequently developed to prepare junctions in a controllable way. SIS microbridge junctions were fabricated (Kingston *et al.*, 1990) using single-layer geometry where noble metals were employed to fill the narrow gap between two HTSg strips. Because of the proximity effect, the ξ near the gap increases to facilitate tunneling. Edge junctions (Gross *et al.*, 1991) were successfully created between one overlying HTSg film and the exposed edge of an underlying HTSg film, which is separated from the top one by an insulating barrier. This method overcomes the difficulties in making multilayer junctions.

More refined junction fabrication techniques were developed to define the location and sometimes even the angle of the grain boundary. One approach is to form a bicrystal by fusing two substrates with different orientations (Dimos *et al.*, 1990). An epitaxial HTSg film deposited onto the bicrystal substrate grows with a well-defined clean grain boundary above the interface between the two substrates. Junctions of excellent quality have been obtained. Unfortunately, the "bicrystal" method is not suitable for preparing a large array of small junctions for complex electronic circuits.

To produce an array of comparable small junctions over a large area with high yield, the "step-edge" approach (Daly *et al.*, 1991) has been used. An epitaxial HTSg film is deposited over a sharply etched step in a substrate. Two clean grain boundaries in the film are created.

Yet another well-controlled "biepitaxial" method with high yield has been recently developed (Char *et al.*, 1991). In this method, one takes advantage of the ability of a thin buffer layer to rotate the in-plane orientation of a HTSg film. For instance, a thin MgO underlying layer changes the orientation of the Y123 film by 45° relative to that of the film without such a buffer layer. Therefore, junctions at the 45°-tilt grain boundary can be formed at any chosen locations at the edges of the MgO seed patches. Unfortunately, 45° is not the optimal tilt angle for the lowest junction noise.

The superconducting quantum interference device (SQUID) (Clarke, 1989) is the most sensitive device available for measuring a variety of physical quantities such as magnetic field, magnetic-field gradient, magnetization, magnetic susceptibility, and many other quantities coupled to the above (see SQUIDs). A dc SQUID consists of two Josephson junctions that are connected in parallel in a superconducting loop. A change in the flux within the loop substantially smaller than a flux quantum Φ_0 with a resolution of $\sim 10^{-6}\ \Phi_0\ \mathrm{Hz}^{-1/2}$ has been detected by a Nb SQUID operated at 4.2 K and at frequencies above 1 Hz. A flux transformer is frequently used in conjunction with the SQUID in order to enhance its field sensitivity, to determine the field gradient, or to couple to other physical quantities to be determined. An rf SQUID consists of one Josephson junction in a superconducting loop that is coupled to a resonant circuit. It is significantly less sensitive than its dc counterpart, although easier to operate.

The LTSg SQUID has already had a significant impact on experimental physics, geophysical surveying, nondestructive testing, precision metrology, and biomagnetism study. SQUIDs that can operate at 77 K will undoubtedly make the applications more common and practical. Because a simpler cryostat can be used with the HTSg SQUID, an increase in sensitivity can also be achieved by reducing the distance between the SQUID and the object generating the magnetic field, e.g., the brain. A HTSg SQUID operated at 77 K has a substantially higher low-frequency noise level than a LTSg SQUID at 4.2 K. However, steady progress has been made in reducing the noise level, as shown in Fig. 25. Practical HTSg SQUIDs can be produced with high enough sensitivities for a wide range of applications. High-performance dc SQUID magnetometers (Koelle *et al.*, 1993) with single-layer Y123 flux transformers have been made with a very low noise level below 10^{-30} J/Hz at 77 K (Koelle, 1994), which is close to that

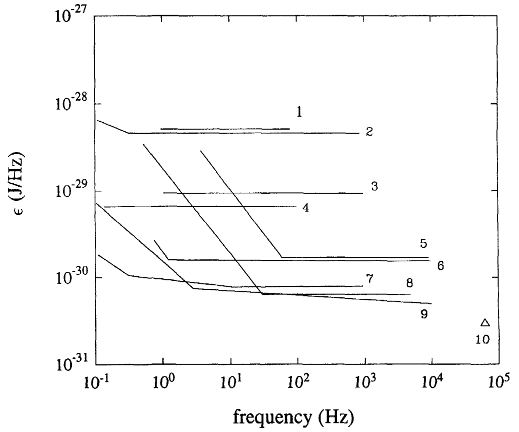

FIG. 25. Energy resolution ϵ for HTSg SQUIDs with different rf and dc SQUID inductances: (1) rf (150 MHz, 190 pH) (Zhang *et al.*, 1993), (2) rf (4.2 K) (Dilorio *et al.*, 1993), (3) (12 pH) (Dilorio *et al.*, 1993), (4) rf (3 GHz) (Mueck, 1993), (5) dc (80 pH) (Sun *et al.*, 1993), (6) dc (20 pH) (Koelle *et al.*, 1993), (7) dc (4.2 K) (Dilorio *et al.*, 1993), (8) dc (10 pH) (Friedl *et al.*, 1993), (9) dc (13 pH) (Koelle *et al.*, 1993), and (10) dc (very small inductance) (Kawasaki *et al.*, 1991).

achieved in commercial LTSg dc SQUIDs operated at 4.2 K.

HTSg multiturn coils have been fabricated by patterning two epitaxial HTSg thin films separated electrically by an insulating layer and by connecting the HTSg coils through openings in the insulating layer. HTSg SQUIDs with biepitaxial junctions were also made on the same substrate in addition to the coils. A SQUID magnetometer was thus fabricated by using a flux transformer to couple magnetic flux into the SQUID (Plate 2). A major step forward was made recently in processing epitaxial HTSr/insulator multilayer films and devices (Miklick *et al.,* 1991). The growth of six epitaxial layers and various steps of patterning, representing most of the technology needed in HTSg electronics, have been achieved by Conductus.

A simple version, "Mr. SQUID" by Conductus, is already commercially available (Fig. 26). Such a device cooled in a hand-held Styrofoam coffee cup has detected MKG signals. A HTSg magnetometer system using a special design has recently been developed to obtain clear 16-channel human heart signals by the Superconducting Sensor Laboratory in Itami, Japan.

5.3 Passive Microwave Devices

Some of the more successful small-current applications of HTSrs have been in the area of passive high-frequency devices. These devices depend on the low surface resistance R_s of HTSg materials to propagate high-frequency signals with lower dissipation and distortion than normal metals. These microwave devices (Newman and Lyons, 1993) include filters, resonators, delay lines, antennas, transmission lines for integrated-circuit chip carriers, etc. The advantages of HTSg materials are primarily in improved performance, which, particularly in the case of antennas and filters, permits the use of compact designs that would not be practical with normal metals.

The R_s of state-of-the-art HTSg thin films at 77 K has been shown in Fig. 16 as a function of frequency. The relative advantages of HTSrs operating at 77 K are not very dramatic in the millimeter-wave region near 100 GHz, but HTSg devices operating at lower frequencies can yield considerable gains. Thus, simple and compact stripline and microstripline thin-film devices can replace waveguide components for narrow-band applications such as delay lines and filters (Fig. 27). As a typical example, a four-pole microstrip band-pass filter at 4 GHz has an insertion loss of only 7% fabricated with HTSrs compared to about 50% when fabricated with Au (the Au filter is unusable in practice). A TBCCO compact dielectric resonator has shown (Shen *et al.,* 1992) quality factors of 2×10^6 with a circulating power of 1 kW at 5.5 GHz and 90 K, 100 times better than a similar resonator constructed using a Au film.

Superdirective antenna arrays are another application where low-loss HTSg materials may be important, especially when the elements are electrically small. Miniaturization is a major concern in antenna applications. Electrically small antennas, less than $\frac{1}{2}$ wavelength long, are attractive below 3 GHz. The

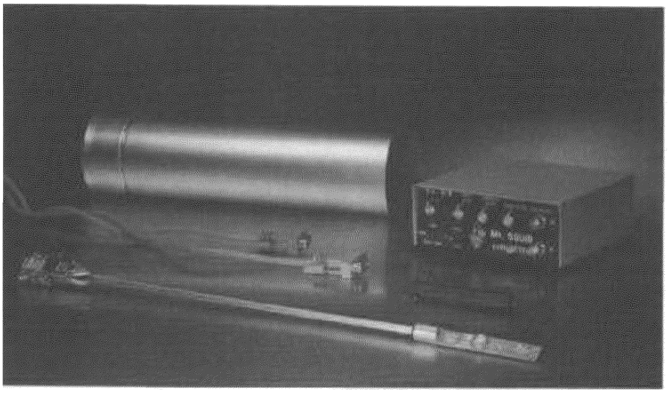

FIG. 26. Mr. SQUID (Conductus). The SQUID sensor is attached to the right-hand side of the holder at the bottom of the picture.

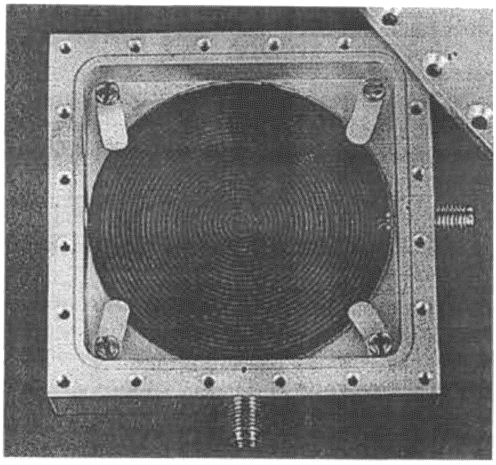
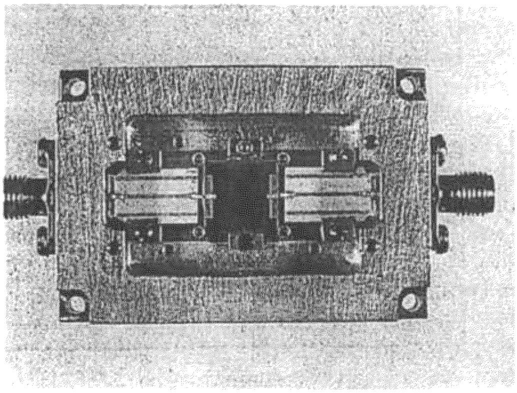


(a)



(b)

price paid in reduced efficiency is largely due to resistive losses in the impedance-matching network between the transmitter and antenna. A Cu matching network for a $\frac{1}{10}$-wavelength dipole antenna would result in a radiation efficiency of the system of 2%, whereas a value of 37% has been achieved with HTSrs. Further increases in efficiency are expected.

5.4 Trapped-Field Magnets

HTSrs are type-II superconductors capable of trapping a magnetic field. This is done by withdrawing the energizing field after cooling a superconductor to below T_c in such a field or by cooling the superconductor in the absence of a field, followed by the application of the energizing field to above H_{c2}. Therefore, they can be used as permanent magnets due to the trapped magnetic field, sometimes even with the high fidelity of the field profile (Weinstein *et al.*, 1990). The advantages of a trapped-field magnet (TFM) include lighter weight, simpler geometry, lower energy consumption, and lower capital cost, in comparison with a conventional electromagnet. A TFM may become the first practical application of bulk HTSrs, bypassing complications associated with the fabrication of HTSg wires.

The trapped field (B_T) is approximately proportional to the J_c and the HTSg-grain size in the sample. Single-grain Y123 disks have been demonstrated by Nippon Steel and the Texas Center for Superconductivity at the University of Houston (TCSUH) to trap a $B_T \sim 1.6$ T at 77 K, a value many times greater than that generated by any permanent magnet. A further increase of B_T toward the limiting value of H_i at 77 K is not inconceivable by continuously increasing the dimensions of the HTSg sample to a critical value of 3 cm diameter (Meng *et al.*, 1994) and/or by enhancing the flux pinning through processing or thorough irradiation by high-energy heavy ions. A record 2.3-T B_T has recently been achieved in a heavy-ion–irradiated HTSg TFM at 77 K by TCSUH. The TFMs are being tested for applications such as magnetic clamps, magnetic rivet guns, magnetic dent pullers, homopolar generators and motors, ultrahigh-field research, and possibly table-top MRI's, which can perform three-dimensional imaging that an electron microscope cannot.

5.5 Magnetic-Mechanical Devices

The demonstration of levitation or suspension, of either a magnet by a HTSr chilled with liquid nitrogen or the inverse, has captured the imagination of experts and nonexperts alike and remains one of the most popular science exhibitions today. It embodies the most fundamental principle of a wide variety of magnetic-mechanical devices such as magnetic bearings, magnetic clutches, vibration dampers, vibration isolators, electromagnetic projectors, magnetic shields, etc.

The phenomenon of magnetic levitation or suspension by HTSrs is a manifestation of the ability of a type-II superconductor to expel or to trap, respectively, an external field originating from a conventional magnet. The prevention of such flux from entering the interior of a HTSr leads to the creation of a supercurrent in the HTSr (but not in the sense of Lenz's law), which generates a field opposite to the field of the magnet. The levitation effect is the result of the interaction between these two fields.

The magnetic flux already in the interior of a HTSr can be trapped by pinning centers and will not leave the HTSr upon the withdrawal of the external field. The interaction between this trapped field and the magnet gives rise to magnetic suspension. A few examples of the HTSg magnetic-mechanical devices are briefly described.

5.5.1 Magnetic Bearings To reduce the friction due to the contact between the surfaces of two objects in relative motion, or to eliminate the need for lubrication, which fails at low temperatures, magnetic bearings of different versions have long been proposed and used. One or more of the magnets act as the rotor and the rest as the stator. The basic concept is to make use of the repulsive force between two similar magnetic poles or the attractive force between two opposite poles. An ideal magnetic bearing should have high thrust (resistance to axial motion) and high stability (resistance to radial motion). Unfortunately, the Maxwell theory of electrodynamics shows that a pair of conventional magnets is intrinsically unstable on account of the existence of a saddle point in a constant-energy surface. In other words, a strong thrust between two magnets in a bearing system in one direction is invariably associated with a strong instability in the other direction (or directions). A complicated servo system is usually used to overcome the instability and makes the bearing bulky and expensive. Therefore, HTSrs, which are not susceptible to this type of instability because of their flux-trapping ability, have been used in conjunction with permanent magnets to construct magnetic levitating bearings with high thrusts. HTSg magnetic bearings are especially attractive for uses below 77 K, such as for liquid-hydrogen pumps, because both the levitation and trapping effects become stronger at these low temperatures. The magnitude of the thrust and the degree of stability depend on the specific arrangement of the magnets and HTSrs.

The simplest form of HTSg magnetic bearing [Fig. 28(a)] consists of a spinning magnet supported by a HTSg disk. Its thrust is determined by the limited levitation or suspension force, and its sideways stability by the field-trapping effect. When similar poles of two magnets are brought close to each other, the thrust increases, but they fly sideways as a result of their instability. On insertion of a slab of HTSr between them [Fig. 28(b)] (Chu *et al.*, 1992), the field-trapping effect overcomes such instability when proper slab thickness and pole strengths are chosen. Similarly, the instabilities can be removed by surrounding the same two opposing-pole magnets with a HTSg cylinder or HTSg blocks [Fig. 28(c)] (Chu *et al.*, 1994). Both the field-repulsive and trapping effects provide the stability to prevent the two magnets from flying away sideways, while high thrust due to the reduced separation between the magnetic poles is realized in this last version. A 19-kg prototype flywheel employing a multistage HTSg bearing (Fig. 29) with an energy loss of 1%/h when running at 6000 rpm has been constructed and tested by TCSUH. A prototype lunar telescope support was also constructed jointly by TCSUH and NASA to overcome difficulties, due to the cold and dusty lunar environment, associated with conventional ball bearings.

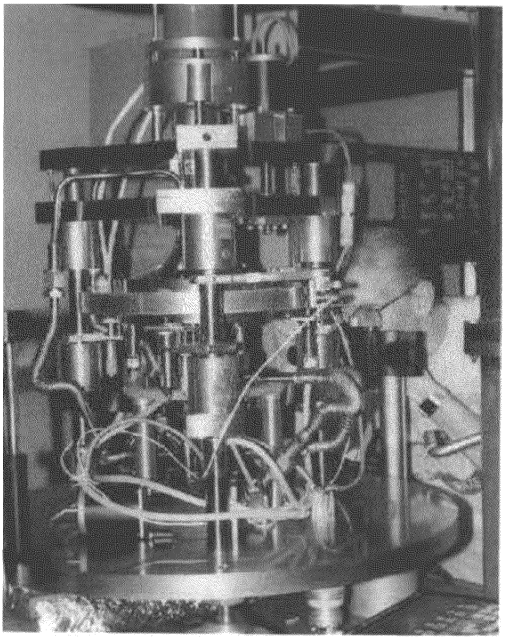

FIG. 29. A 19-kg flywheel supported by HTS magnetic bearings (Chu *et al.*, 1995).

5.5.2 Vibration Dampers and Magnetic Clutches Because of the field-trapping effect, any change of magnetic field experienced by a HTSr leads to energy dissipation. In other words, it requires a force to move a magnet across a HTSr. It was proposed (Ma *et al.*, 1992) to amplify such a force by adopting a multipole configuration. Any linear or rotational motion of the magnets with respect to the HTSrs generates rapid cyclic variations of fields across the HTSrs and therefore a large dissipative force. Clutches [Fig. 30(a)] and vibration dampers [Fig. 30(b)] have been constructed and tested, with the object to be damped or coupled attached to the multiple-magnet assembly, which is placed near but not in contact with a HTSg slab fastened to its surrounding. The various modes of coupling between the magnets and the HTSr can be tuned by varying the temperature of the HTSr or by auxiliary fields generated by simple small electromagnets. Using the vibration damper arrangement, a prototype was constructed by TCSUH to support a scanning tunneling microscope with a minimum vibration to enhance the resolution.

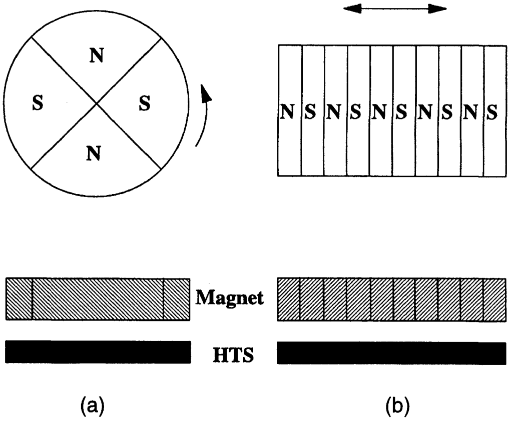

FIG. 30. Different HTS/magnet assemblies for (a) clutches and (b) vibration dampers (Chu *et al.*, 1992).

5.6 Electrodes, Fault-Current Limiters, and Power-Transmission Cables

In many applications of LTSrs, large currents have to be transferred from room temperature to the 4.2-K operating environment. Heavy Cu cables with low electrical resistance are usually used to reduce Joule heating and, thus, energy waste and liquid-helium evaporation. Unfortunately, Cu is also a good thermal conductor, which leads to a large helium boiloff. Melt-textured Y123 has a large J_c and very low thermal conductivity, several hundreds to a thousand times smaller than Cu (Fig. 18). Long melt-textured rods with a large cross section can be used as electrodes to transmit large currents from 77 to 4.2 K. Y123 bars ~10 cm long and with a $0.4 \times 0.4\text{-cm}^2$ cross section have been prepared at TCSUH to carry a total critical current up to 1000 A at 77 K. Rods are also easily made of sintered Y123 with high dimensional precision by extrusion to carry a total current of 125 A. An electrode consisting of many sintered Y123 rods was reported by Argonne National Laboratory as capable of carrying a critical current of 2×10^3 A. General Electric Company has developed a magnetic resonance imaging system requiring no liquid cryogen, using HTSg electrodes as current leads, as shown in Fig. 31.

Falling power lines or lightning can cause "fault currents," momentary spikes many times greater than normal operating currents, making it necessary to safeguard gen-

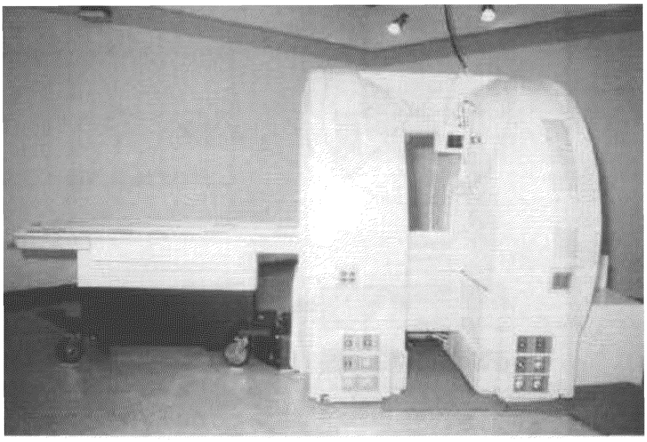

FIG. 31. An MRI that requires no liquid cryogen to operate, using HTSg electrodes for current leads (General Electric).

erators, transmission lines, and transformers and to minimize the down time to reduce customer inconvenience. An HTSg current limiter limits the current flow by switching from a nonresistive superconducting state to a resistive normal state when subjected to the fault current. An effective current limiter is required to consume no energy during its normal operation and to have a very short switching time, e.g., less than 0.1 s. The demand on HTSg material by such a device is rather stringent in terms of large J_c, large normal-state resistance, and small thermal volume. Several device concepts have been proposed and are being pursued (Giese *et al.*, 1994).

A HTSr-based power-transmission system must be a long-term effort. Because of the required refrigeration, use of such a system will be limited to underground lines. The Electrical Power Research Institute (EPRI) has identified two areas where HTSg power-transmission systems appear to have compelling advantages over conventional systems (Dales *et al.*, 1990). The first is to retrofit existing underground circuits in congested urban areas in order to increase the power ratings. The other is for underground lines longer than 25 miles, where conventional systems require large and expensive inductors every 20 miles or so. American Superconductor Corporation has fabricated a 1-km length of HTSg wire with a $J_c \sim 13\,800$ A/cm^2 and a total critical current of 16 A. They have also made a 1-m flexible cable (of diameter $\sim$5 cm, including the supporting structure) that can carry a total current of 4200 A at 77 K without loss. The target for major cable applications is HTSg cables with a $J_c \sim 20\,000$–$200\,000$ A/cm^2 in kilometer lengths.

6. FUTURE TRENDS

It has long been known that superconductivity offers both unusual scientific challenge and great technological potential. The discovery of superconductivity above 77 K in 1987 heralded a new era of high-temperature superconductivity. As a result, many applications of superconductors appear to be more practical than ever before. Enormous effort has thus been devoted to the study of HTSy, and impressive progress has subsequently been made at an unprecedentedly fast pace since 1987. As described in the previous sections, more than 90 compounds with a T_c higher than 23 K and more than 30 with a T_c higher than 77 K have been discovered. Many physical properties characteristic of the HTSg materials that are significant to the understanding and use of HTSrs have been determined, various theoretical models to account for these properties proposed, and numerous processing techniques to improve the performance of HTSrs for scientific pursuit and practical applications developed. Many old concepts for the application of superconductivity have been demonstrated using HTSrs, and new concepts are being tested, prototypes of some HTSg devices are being built and tested, and even a few HTSg products are already commercially available.

In spite of the great effort devoted to HTSy and the impressive progress made in HTSy, several important scientific questions have yet to be answered, and viable commercial products have yet to be identified. A few questions by way of example might illustrate this: What is the underlying mechanism responsible for HTSy? What is the symmetry of the HTSg order parameter? What is the dimensionality of HTSy? Can HTSy (especially for a $T_c > 77$ K) exist in a truly three-dimensional or isotropic electron system? Is there a T_c ceiling; if so, what is it? As T_c becomes higher and higher, will ξ become shorter and shorter, making $\rho = 0$ and $B \neq 0$ for a HTSr in an operational sense? What is the genuine H-T phase diagram of a HTSr, especially between H_i and H_{c2}? While answers to these questions might seem to be purely academic, they will have major impacts on HTSg technology. On the application front, many of the HTSg device prototypes that have been built and tested will no doubt have important roles in HTSg technology, but the economic impact of any device is still not clear.

To a great extent, the impasses that are faced to develop fully the HTSy science and technology are material based. There is a need for HTSg materials of high quality and large dimensions, and (if possible) noncuprate based. This will enable the research community to carry out the critical experiments to unravel the mystery of HTSy and thus make possible the development of a comprehensive HTSy theory that is simple, general, descriptive, and predictive as well. The chemistry of HTSg materials is rather complicated. A systematic study of the phase equilibria of these material systems will enable one to achieve the material quality needed for scientific study, to improve the material performance to that required for applications, and to provide guidance to the discovery of new HTSg compounds. The search for noncuprate HTSrs will help reveal if Cu plays an indispensable role in HTSy, a concept on which a great majority of the known HTSy theories is based. Attempts to synthesize these novel materials under extreme conditions, e.g., high pressure or fast quenching, may prove to be fruitful.

Many reports of anomalies in oxides suggestive of a superconducting transition at temperatures above 200 K have appeared (Levi, 1994; Service, 1994) after the discovery of HTSy. They usually involve a small drop in resistivity (but not to zero) or a small diamagnetic shift in susceptibility (but only superimposed on a large paramagnetic background). They display poor reproducibility, not just from laboratory to laboratory and from sample to sample, but also from run to run of the same sample. Some of these fleeting anomalies have been shown to arise from experimental artifacts. Others are known at best as unidentified superconducting objects (USOs). The numerous persistent reports of resistive (or magnetic) anomalies in multiphase cuprates from many credible laboratories in the temperature range of 150–300 K are too tantalizing to ignore. It has been conjectured that the absence of a clear Meissner effect may be a result of the ever-increasing difficulty to detect the effect due to the ever-decreasing coherence length as T_c increases. There presently exists no theory that sets a T_c limit in oxides. However, the possibility that the cause of the reported resistive anomalies is the sensitive dependence of oxide resistance on humidity and gases has not yet been ruled out completely.

Conflicting characteristics of HTSrs from different types, and sometimes the same type, of experiments have been reported, e.g., some results support d pairing but others favor s pairing. While sample quality has often been the suggested reason for the inconsistent reports, the complex chemistry of HTSg materials and the possible interaction of the experimental probe with the HTSg sample may have complicated the experiments. Extra caution is thus needed to perform the experiments and to interpret the observations. The implication of the pairing symmetry in the HTSg mechanism needs more study.

HTSg material processing will play a critical role in making applications of HTSrs practical. The material has to be made with the optimal superconducting properties (e.g., high T_c and J_c), the desired dimensions (e.g., long length and large cross section for larger-current applications, or large-area thin film for some small-current uses), and required forms (e.g., wires or films) for devices, all at low cost. Techniques for device fabrication with high yield at low cost are equally important. Ultimately, it will be the cost that differentiates success from failure in the commercialization of the product.

While a quantum leap is always welcome in science and technology, incremental improvement should never be overlooked. Insertion of HTSg devices into an existing system, to improve the system performance, such as the successful use of HTSg filters to enhance the capacity of a mobile phone base station, is one such example. Although many concepts for the application of HTSrs have been successfully demonstrated, other significant commercial uses of HTSrs that are currently unforeseen may be discovered. They may include the use of the normal-state properties of HTSrs.

ACKNOWLEDGMENTS

The author would like to thank the many scientists and engineers who have contributed to the progress made in HTSy to date, without whom this article could not have been written. He would like to express his great appreciation to his colleagues at TCSUH, particularly Y. Y. Xue and F. Chen for their help in compiling some of the information and preparing the figures. He is also grateful to George Trigg, the editor, and to Lorin Vant-Hull, Donn Forbes, and Mike Albert, who have made valuable suggestions that helped make the article more readable. The work is partially supported by NSF, EPRI, and TCSUH.

INTRODUCTION

Superconductivity, the disappearance of the dc electrical resistivity of a material cooled below a characteristic temperature, is a fascinating phenomenon that has attracted the interest of physicists since its discovery in 1911. From the very beginning, researchers have been attracted not only by the wealth of interesting physical phenomena associated with superconductivity, but also by the technological applications that are imag-

inable with the prospect of circulating electrical current in superconducting wires with virtually no losses.

Today, with many well-established applications of superconductivity at both large and small scales and a renewed interest in the mechanisms and phenomena associated with superconductivity that was sparked by the discovery of new classes of superconductors in the years since 1986, superconductivity remains an exciting field of condensed-matter physics with many interesting questions remaining to be answered.

Brief History of Superconductivity

In the year 1908, the noble gas helium was liquefied for the first time by H. Kammerlingh Onnes at Leiden, thus allowing the achievement of low temperatures that were inaccessible before. In 1911, investigating the low-temperature electrical resistance of metals, Kammerlingh Onnes observed that the resistance of a mercury sample sharply dropped to immeasurably small values at about 4.15 K and called the new state of matter characterized by vanishing electrical resistance "superconductivity." (Mercury was chosen because it could be obtained in very pure form by simple distillation.) Shortly thereafter, he also observed the suppression of electrical superconductivity by currents, establishing the concept of critical currents (see Sec. 1.4). In 1912, Kammerlingh Onnes found tin and lead to be superconducting, a discovery that made experiments on wires and coils much easier compared to the brittle and mechanically unstable threads of frozen mercury. He was awarded the Nobel prize in physics for the year 1913 for "his investigations on the properties of matter at low temperatures." Early 1914 saw the discovery of the existence of a threshold magnetic field above which superconductivity is suppressed, the critical magnetic field (see Sec. 1.3). Furthermore, the first experiments devised to determine the time constant of the decay of a current circulating in a superconducting loop and thus of an upper limit for the residual resistance of the superconductor were performed, demonstrating the presence of persistent currents (see Sec. 1.1).

In 1916, F. B. Silsbee hypothesized that the critical current is the current that produces the critical field at the surface of a superconductor, thus explaining the critical current as a consequence of the existence of a critical magnetic field. New superconductors were discovered at Leiden in 1919 (thallium and the lead isotope ^{206}Pb) and in 1922 (indium). It was not possible, at that time, to detect any sizable variation of the superconducting transition temperature T_c with the atomic mass (the so-called isotope effect; see Sec. 1.7).

With further laboratories becoming able to perform experiments at liquid-helium temperatures, in the course of the following years, more elements and, to an increasing extent, binary alloys were found to be superconducting, some of which exhibited critical fields orders of magnitude higher than those of the superconducting elements. This put practical applications—e.g., superconducting magnets (see Sec. 4.1)—within reach.

In 1932, the specific-heat jump associated with the superconducting transition in zero field was observed in tin and thallium, again at Leiden.

The second characteristic property of the superconducting state, the complete expulsion of magnetic flux from the interior of a superconductor, was discovered in 1933 by W. Meissner and R. Ochsenfeld. The observation of the Meissner effect established the superconducting state as a distinct thermodynamic equilibrium phase (see Sec. 1.2.1). Shortly thereafter, the concept of the intermediate state (see Sec. 1.3.2) was established.

In 1935–1936, the magnetic properties of type II superconductors with their two characteristic fields above which field penetration and restoration of resistance set in were uncovered by L. V. Shubnikov. Magnetization measurements provided conclusive evidence for the existence of the mixed state where magnetic flux partially penetrates the superconductor.

The theoretical description of the electrodynamics of superconductors was attempted in a phenomenological theory by the brothers F. and H. London in the mid 1930s. Their theory incorporated the Meissner effect and defined a characteristic penetration depth for the magnetic field (see Sec. 1.2.2).

Another phenomenological description of the superconducting state was proposed by C. J. Gorter and H. B. G. Casimir in 1934. Their two-fluid model assumed that "superconducting" electrons that are responsible for the infinite conductivity and "normal" electrons that undergo scattering are present in the superconductor at the same time, with the fraction of superconducting electrons adjusting itself for any temperature and field so that the free energy is minimized, assuming the limiting values of 1 at zero temperature (only superconducting electrons) and 0 at the transition temperature (no superconducting electrons).

The first measurements of the magnetic penetration depth were performed by D. Shoenberg in 1940, who investigated the temperature dependence of the magnetic susceptibility of colloidal suspensions of mercury spheres.

On the basis of measurements of the surface resistance of tin and mercury resonators at microwave frequencies, A. B. Pippard developed the concept of a minimum coherence length for the spatial variation of the parameters characterizing the superconducting properties (see Sec. 1.3.3.1).

The year 1950 brought the publication of a comprehensive phenomenological theory by V. L. Ginzburg and L. D. Landau (GL), which modeled the free-energy density of a superconductor as a functional of a superconducting order parameter and was able to describe successfully both type I and type II superconductivity, with a characteristic quantity, the Ginzburg–Landau parameter, distinguishing between these two cases (see Sec. 2.2).

Also in 1950, the dependence of the superconducting transition temperature on the atomic mass of the superconducting element, the isotope effect that Kammerlingh Onnes had not been able to detect in the 1920s, was verified experimentally. Almost in parallel, H. Fröhlich had developed a theory that predicted the very same effect using the assumption of an indirect interaction between electrons mediated by lattice vibrations (phonons). Although this theory failed to explain the Meissner effect, its concept of an electron–phonon interaction was developed further by J. Bardeen, L. N. Cooper and J. R. Schrieffer (BCS), who published their microscopic theory of superconductivity in 1957. It predicted the formation of electron pairs of spin zero (Cooper pairs) as the consequence of an attractive electron interaction by virtue of the exchange of virtual phonons (see Sec. 2.1). The BCS theory successfully reproduced the crucial experimental facts such as the existence of an energy gap in the electronic excitation spectrum, the Meissner effect, and the isotope effect.

Also in 1957, A. A. Abrikosov predicted that the equilibrium flux configuration in the mixed state of type II superconductors is characterized by the penetration of the magnetic field into the superconducting material in the form of flux lines or Abrikosov vortices (see Sec. 1.3.3.2).

On the materials side, more superconductors with higher transition temperatures and critical fields were discovered in the 1950s, many of them by B. T. Matthias and J. K. Hulm. An empirical rule established by Matthias correlated high transition temperatures (and high electronic specific-heat coefficients) with peaks in the average ratio of valence electrons to the number of atoms.

In the early 1960s, the technological development was characterized by the construction of superconducting, iron-free solenoids from intermetallic materials such as Nb_3Sn and Nb-Ti that not only possessed extremely high critical fields but were also able to sustain large electrical currents in the presence of these fields.

In 1962, B. D. Josephson predicted the existence of a constant dc current across a junction where two superconductors are separated by a thin insulating or normal barrier. This current is due to the tunneling of electron pairs across the barrier and exhibits a characteristic modulation as a function of the magnetic flux threading the junction. Furthermore, in the presence of a potential difference across the barrier, there should be an alternating current flowing whose frequency is determined by the potential difference. These dc and ac Josephson effects were verified experimentally shortly thereafter and soon utilized in extremely sensitive magnetic-field sensors and other applications (see Sec. 4.2).

In 1967, magnetic-flux lines were imaged for the first time using a magnetic decoration technique (see Sec. 1.3.3.2), confirming the existence of the Abrikosov vortex lattice.

By 1973, the record value of the superconducting transition temperature T_c was 23.2 K for the intermetallic compound Nb_3Ge. It remained there for 13 more years, with many researchers believing that an upper limit had been reached that could not be surpassed. In early 1986, however, J. G. Bednorz and K. A. Müller discovered superconductivity at temperatures as high as 30 K in an oxide system, Ba-La-Cu-O, triggering an immense worldwide research effort that resulted in the discovery of ever new superconducting compounds with increasingly higher transition temperatures. The significance of this development is illustrated in Fig. 1, where the maximum superconducting transition temperature T_c is plotted as a function of time.

After this breakthrough, all the materials known before with transition temperatures below ~30 K are classified as low-temperature superconductors, as opposed to the new high-temperature superconductors that are the subject of a separate article (see SUPERCONDUCTIVITY, HIGH-TEMPERATURE).

1. BASIC PROPERTIES OF SUPERCONDUCTORS

1.1 Zero Resistivity (Infinite Conductivity)

When a superconductor is cooled below a characteristic temperature, called the superconducting transition temperature or critical temperature T_c, its dc electrical resistance R becomes immeasurably small and is assumed to be zero. Superconductors are therefore considered to be ideal conductors; their conductance G is infinite. Thus, the time constant $\tau = L/R$ for the decay of an electrical current I circulating in a ring made of superconducting material with self-inductance L is infinite, and such a current is termed a persistent current or supercurrent. From time constants that were found to be of the order of years, changes of up to 18 orders of magnitude in the resistance of samples undergoing the superconducting transition were inferred. This transition can be extremely sharp (a few microkelvins) in very clean samples and broadens with increasing density of impurities and/or structural defects (see Fig. 2). Values for T_c range from a few microkelvins to more than 150 K (see Sec. 3), spanning many decades of the thermal energy k_BT_c ($k_B = 1.38054 \times 10^{-23}$ J K^{-1} is the Boltzmann constant).

Superconductors may exhibit a finite ac resistance at frequencies that are higher than about $2\Delta(T)/\hbar$, where $2\Delta(T)$ denotes the superconducting energy gap (see Sec. 1.5) and $\hbar = 1.0545 \times 10^{-34}$ J s is Planck's constant.

1.2 Ideal Diamagnetism

1.2.1 Meissner Effect Superconductors are not only perfect conductors; they are also perfect diamagnets. In an external magnetic

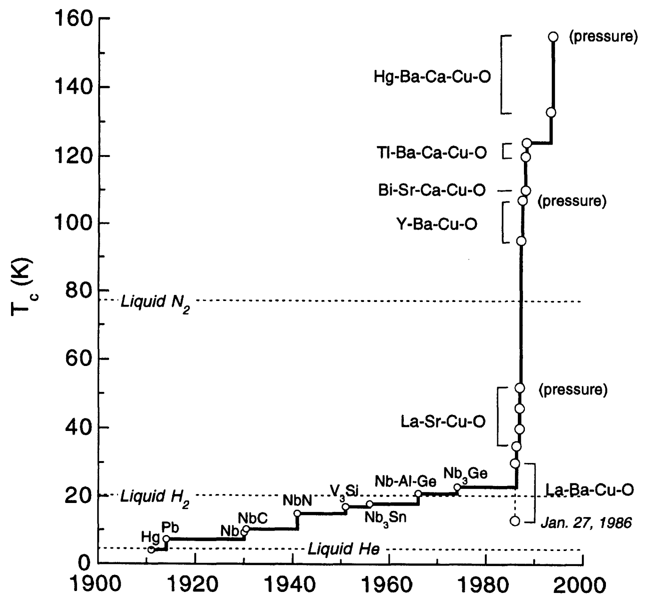

FIG. 1. Development of the maximum superconducting transition temperature over time.

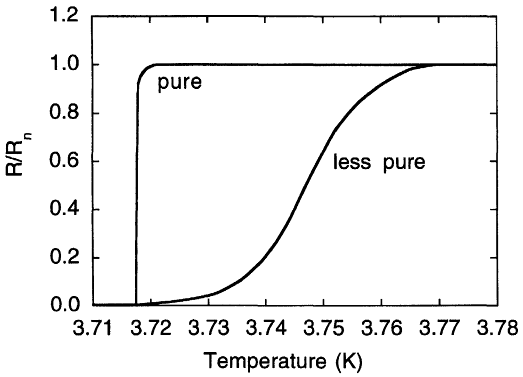

FIG. 2. Temperature dependence of the zero-field electrical resistance $R(T)$, normalized with respect to its normal-state value R_n, for a clean and a dirty superconductor (here: single-crystalline and polycrystalline tin). The resistive transition broadens with increasing number of impurities and/or defects.

field H_a that is smaller than a characteristic field H_c (see Sec. 1.3), the interior of a superconductor remains field free, i.e., any magnetic flux Φ is expelled, and hence the magnetic-flux density B is zero throughout the sample.

In principle, two different paths in the H-T phase space that bring the sample into a state with $H_a < H_c$ and $T < T_c$ can be followed (see Fig. 3). The sample is either cooled down to $T < T_c$ in zero applied field, and then $H_a < H_c$ is switched on (zero-field cooling, ZFC), or the cooldown process takes place with the external field H_a applied (field cooling, FC). In the first case, the superconductor is indistinguishable from a perfect conductor: According to Lenz's law, upon switching on the external field, supercurrents are induced in the sample that compensate the change of the magnetic flux through the sample, producing a diamagnetic magnetization M that cancels the applied field, so that $B = \mu_0(H_a + M) \equiv 0$ everywhere in the sample. Here, $\mu_0 = 4\pi \times 10^{-7}$ H/m (V s A^{-1} m^{-1}) is the vacuum permeability, and the vector character of **B**, **H**, and **M** is neglected, as are demagnetization effects due to the sample geometry (see Sec. 1.3.2). In the FC case, however, the perfect conductor, once penetrated by the external field at $T > T_c$, would remain in that state upon cooling, since there is no change in the magnetic-flux density that would induce screening currents, whereas the superconductor expels the flux from its interior upon cooling through the superconducting transition.

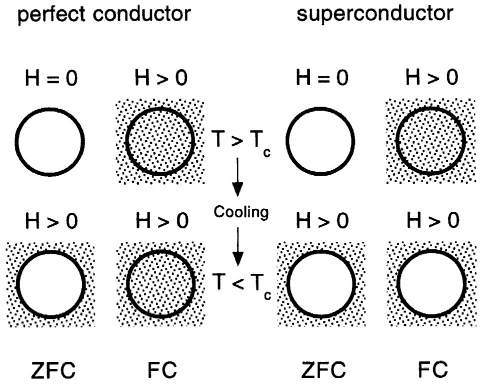

FIG. 3. Response of a perfect conductor (left) and of a superconductor (right) to an external magnetic field. Upon zero-field cooling (ZFC), both samples screen the external field. Under field cooling (FC), however, the field remains inside the perfect conductor, whereas it is expelled from the superconductor (Meissner effect).

The fact that $B = \mu_0(H_a + M) = \mu_0(1 + \chi)H_a \equiv 0$ in a superconductor implies that the volume susceptibility χ equals -1 (ideal diamagnetism). This fundamental property of superconductors that establishes the superconducting phase as a true thermodynamic equilibrium state (see Sec. 1.3.1) is named the Meissner effect. It provides the conclusive test to experimentally distinguish a superconductor from a perfect (or very, very good) conductor.

1.2.2 Magnetic Penetration Depth

The screening or shielding currents that create a magnetization canceling the external field and keeping the superconductor's interior field free circulate only in a thin surface layer. This fact is described by the phenomenological equation

$$\nabla^2 \mathbf{B} = (1/\lambda^2)\mathbf{B},$$

which incorporates the condition that $\mathbf{B} \equiv 0$ throughout the superconductor and, together with the Maxwell equation $\nabla \times \mathbf{B} = \mu_0 \mathbf{j}$, permits the calculation of the distribution of the magnetic-flux density **B** and the supercurrent density **j** in the sample. It yields the magnetic penetration depth λ as the characteristic length scale over which fields and currents decay in the interior of the superconductor. Typical values for λ for low-T_c superconductors—extrapolated to $T = 0$—are of the order of 10 nm, so that most macroscopic samples with dimensions much larger than λ can be considered field free. However, this may not be true for certain sample geometries (see Sec. 1.3.2).

The penetration depth λ varies for different superconducting materials, often changes with the orientation of the external magnetic field with respect to the sample, and depends on temperature, saturating at low temperatures with $\lambda(T = 0) \equiv \lambda_0$ and rapidly increasing while approaching T_c. For many superconductors, this dependence is described by the empirical relation

$$\lambda(T)^2 = \lambda_0^2 \frac{T_c^4}{T_c^4 - T^4}.$$

The magnetic penetration depth λ is an important physical quantity characterizing a specific superconductor. Among the methods employed to determine λ are the measurement of changes in the self or mutual inductance of the superconducting components of rf circuits, in the magnetic volume susceptibility, or in the surface impedance of superconducting films at microwave frequencies, as well as the measurement of the depolarization rate of spin-polarized muons, which provides information about the local magnetic field inside the superconductor.

1.3 Critical Magnetic Fields

1.3.1 Type I Superconductivity The superconducting state is strongly influenced by the presence of a magnetic field: For fields higher than a characteristic temperature-dependent field, the critical field H_c, superconductivity is suppressed, and the sample becomes normal conducting. The shielding supercurrents break down, and the external magnetic field completely penetrates the sample. A material characterized by this behavior is called a type I superconductor, and many of the metallic elements belong to this class (see Sec. 3). The critical field decreases with increasing temperature, typically following the empirical relation

$$H_c(T) = H_c(0)[1 - T^2/T_c^2].$$

The extrapolated zero-temperature critical field $H_c \equiv H_c(0)$ is of the order of 10^4–10^5 A m^{-1} ($\sim 10^2$–10^3 Oe) for typical type I superconductors (see Sec. 3).

The $H_c(T)$ line separates the superconducting and normal states in the H-T phase plane. Since the difference in the Gibbs free-energy density $\Delta g \equiv g_n(T) - g_s(T)$ between these two phases is equivalent to the magnetic energy density,

$$\Delta g(T) = -\mu_0 \int_0^{H_c(T)} M(H,T)dH = \frac{\mu_0}{2} H_c^2(T),$$

knowledge of the $H_c(T)$ curve allows the determination of important thermodynamic quantities such as the entropy change, the specific-heat jump, and the latent heat associated with the phase transition. Therefore, H_c is also referred to as the thermodynamic critical field. In zero magnetic field, the phase transition is of second order, whereas in the presence of a magnetic field, it becomes a first-order transition.

1.3.2 Intermediate State The simple picture of magnetic flux uniformly penetrating a type I superconductor in fields higher than the critical field H_c is strictly valid only for samples whose dimension parallel to the external field is infinite (long, thin slabs with the field along the axis or thin plates with the field in the plane are good approximations). If the magnetization of the sample has components perpendicular to the direction of the external field, surface magnetic charges or free magnetic poles create stray fields known as "demagnetizing" fields. If the sample is homogeneously magnetized (which is the case for ellipsoidal sample geometries), the demagnetizing field H_d is proportional to the magnetization M and given by $H_d = NM$, with the demagnetization factor N assuming its maximum value of unity for the case of an infinite plate perpendicular to the field and its minimum value of zero when the field is along the axis of a long, thin slab or in the plane of a thin plate (again, the vector character of **H** and **M** as well as the tensor character of **N** and χ are neglected here). Then, the effective field experienced by the sample can be expressed as

$$H_{\text{eff}} = H_a - NM = H_a - N\chi H_{\text{eff}},$$

or

$$H_{\text{eff}} = \frac{1}{1 + N\chi} H_a.$$

In superconductors, $\chi < 0$, so that $H_{\text{eff}} > H_a$. Since the tangential field component has to be continuous, this implies local field enhancement, e.g., at the equator of spherical samples. Thus, there exists a field interval in which the external field is larger than H_c on some points at the sample surface and, at the same time, lower than H_c on other points. In this case, it is energetically most favorable for the superconductor to split up into superconducting and normal domains, and the sample is said to be in the intermediate state. The size of the normal domains can be of the order of millimeters and increases with field. Demagnetization effects due to the sample geometry can completely dominate the magnetic response of a superconductor, especially in the case of thin platelets oriented perpendicular to the field.

1.3.3 Type II Superconductivity Below a characteristic, temperature-dependent field called the lower critical field $H_{c_1}(T)$, a type II superconductor is completely equivalent to a type I superconductor for $H < H_c$: $B = 0$, $M = -H$; the sample is considered to be in the so-called Meissner state. If the applied field exceeds another characteristic field, the upper critical field $H_{c_2}(T)$, the sample enters the normal state, and magnetic flux completely penetrates its interior. In the intermediate field interval $H_{c_1} < H < H_{c_2}$, however, a new phase develops that is characterized by the partial entry of magnetic flux into the sample and is called mixed state or Shubnikov phase. Schematic H-T phase diagrams for a type I and a type II superconductor are shown in Fig. 4.

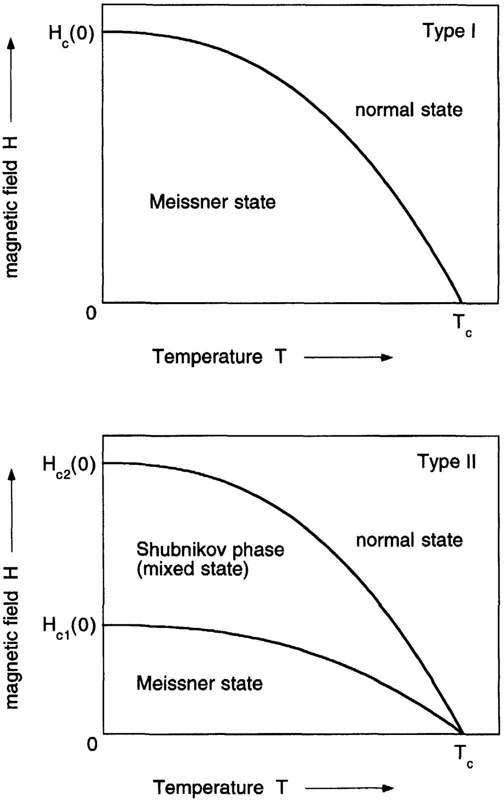

FIG. 4. Schematic illustration of the *H-T* phase diagram for type I and type II superconductors.

1.3.3.1 Superconducting Coherence Length. Aside from the penetration depth λ, which describes the distance over which screening supercurrents and magnetic fields decay inside a superconductor, there is another important length scale characterizing the spatial extent of the attractive correlation between the electrons that gives rise to superconductivity (see Sec. 2). This coherence length ξ, which is of the order of tens to thousands of nanometers for low-T_c superconductors (see Sec. 3) also represents a typical distance over which changes in the density of the superconducting charge carriers occur.

The ratio of the two characteristic lengths $\kappa = \lambda/\xi$ is called the Ginzburg–Landau parameter of the superconductor. Materials with $\kappa < 1/\sqrt{2}$ are type I superconductors, whereas $\kappa > 1/\sqrt{2}$ describes type II materials. Figure 5 illustrates these two situations and demonstrates that in the latter case, a negative surface-energy density may arise. It is due to this negative surface energy that a type II superconductor splits into superconducting and normal regions, the latter being penetrated by the external magnetic field.

1.3.3.2 Abrikosov Vortex Lattice. The energetically most favorable configuration of superconducting and normal domains in the mixed state corresponds to the penetration of magnetic flux in the form of so-called Abrikosov vortices or flux lines. These vortices are comprised of a normal "core" region

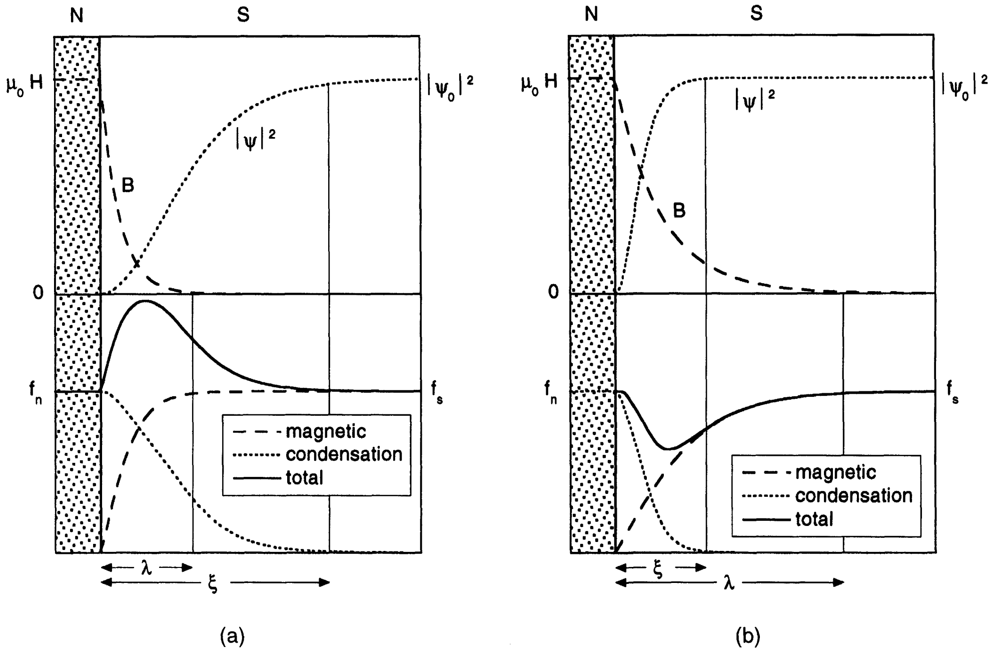

FIG. 5. Schematic illustration of the spatial variation of the magnetic flux density B and Cooper-pair number density $|\psi|^2$ at the interface between a normal metal N and (a) a type I and (b) a type II superconductor S. Also shown are schematic representations of the contributions to the free-energy density due to magnetic and condensation energy, and the resulting positive and negative surface energies.

of radius $\sim\xi$ parallel to the external field, where the density of the superconducting charge carriers is strongly reduced, and supercurrents circulating around the core, which screen the field over a distance λ. In clean (i.e., defect-free) type II superconductors, the vortices arrange themselves in a regular hexagonal pattern known as the Abrikosov vortex lattice, as illustrated in Fig. 6. Experimentally, vortices are imaged using magnetic decoration techniques where fine magnetic particles that accumulate at the regions of high-flux gradients on the sample surface corresponding to the vortex positions are observed by electron microscopy. Other methods include small-angle neutron scattering, scanning probe microscopy with miniature Hall probes as the magnetic sensor, and magneto-optical techniques (the latter can only resolve bundles of flux lines but are capable of imaging their dynamics).

1.3.3.3 Magnetic Fluxoid. It is not the magnetic flux threading a superconducting loop that is conserved by supercurrents counterbalancing flux changes, but rather the so-called fluxoid

$$\Phi \equiv \iint_S \mathbf{B}\cdot d\mathbf{s} + \mu_0\lambda^2 \oint_L \mathbf{j}\cdot d\mathbf{l},$$

where the first term represents the magnetic flux through the loop cross section S and the

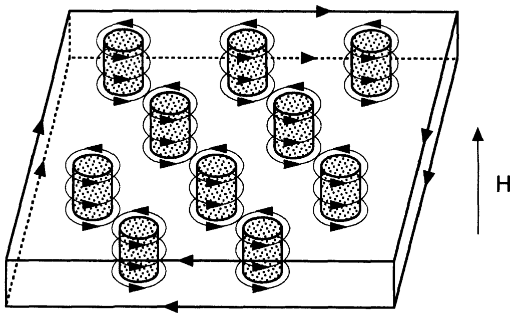

FIG. 6. Schematic illustration of the penetration of an external magnetic field H into an ideal type II superconductor in the form of hexagonally arranged flux lines or vortices, forming the Abrikosov flux lattice. Screening currents flowing on the sample periphery create a diamagnetic magnetization, whereas the vortices can be imagined to be surrounded by opposite supercurrents.

second term is the line integral of the supercurrent density around the loop L. The fluxoid is quantized in units of the magnetic-flux quantum $\Phi_0 = h/2e = 2.07 \times 10^{-15}$ Wb (V s), where $e = 1.602 \times 10^{-19}$ C (A s) is the elementary charge. Flux quantization is a consequence of the requirement that the macroscopic superconducting wave function (see Sec. 2) is single valued, so that its phase can only change by integer multiples of 2π upon circumfering the loop on a path well inside the superconductor where the field is zero.

In the mixed state, each flux line carries one flux quantum.

1.4 Critical Current Density

The superconducting properties of a conductor carrying a transport electrical current I with current density j are suppressed when j exceeds a characteristic value, the critical current density j_c. Aside from the transition temperature $T_c(H)$, the temperature- and field-dependent critical current density $j_c(T,H)$ is that parameter characterizing a superconductor that is most relevant for large-scale technological applications (see Sec. 4), since it marks the onset of dissipation in the form of resistive losses.

For type I superconductors, $j_c > 0$ for $T < T_c$ and $H < H_c$. In this case, a finite resistance is observed whenever the total magnetic field corresponding to the superposition of the applied field H and the field generated by the transport current exceeds the critical field H_c anywhere at the surface of the sample. For $H = 0$, the critical current will be that current that creates the critical field H_c at the conductor's surface (Silsbee's rule).

For type II materials, a modification of Silsbee's rule applies to the Meissner state ($H < H_{c1}$), when H_{c1} is substituted for H_c. In the mixed state, however, j_c is not necessarily nonzero for $T < T_c$ and $H < H_{c2}$. For an ideal sample, where the interacting flux lines form an undisturbed Abrikosov lattice, an arbitrarily small force acting on the vortices (such as arising from a transport current or from a changing field) induces vortex motion and, therefore, dissipation. For this reason, in clean type II superconductors, j_c is very small in the mixed state. On the other hand, if there exist regions inside the superconductor where the superconducting order parameter (see Sec. 2.2) and the density of superconducting charge carriers are reduced locally, the presence of a flux line's normal core at such a location is energetically favored compared to its presence in a fully superconducting region because, in the latter case, the energy necessary to suppress superconductivity in that region is higher than in the former case. Therefore, such regions represent pinning centers for the flux lines that prevent vortex motion, and the associated pinning forces determine the temperature and field dependences of the critical current density. These forces (or the respective pinning potentials) depend on the nature of the defects, especially on their size. High pinning forces have been achieved in various alloys, resulting in superconducting materials with very good current-carrying capabilities in high magnetic fields (see Secs. 3 and 4). These materials are referred to as "hard" type II superconductors.

1.5 Energy Gap

In the framework of the microscopic theory for low-T_c superconductivity (see Sec. 2.1), the superconducting charge carriers are Cooper pairs of electrons that form as a result of an attractive interaction between electrons that is mediated by lattice vibrations (phonons). Because the binding or condensation energy of these pairs has to be overcome in order to break them apart, there is a temperature-dependent superconducting energy gap $2\Delta(T)$ in the electronic excitation spectrum of these superconductors. The temperature dependence of the energy gap $\Delta(T)$ close to T_c is predicted by the microscopic theory (see Sec. 2.1) as

$$\Delta(T) \propto T_c(1 - T/T_c)^{1/2}.$$

The existence of the energy gap manifests itself in a variety of experiments.

1.5.1 Specific Heat The low-temperature specific heat $C(T)$ of a metal can be described by the sum of a lattice contribution $C_1(T)$ and an electronic contribution $C_e(T)$. The lattice term $C_1 \propto T^3$ does not change when the metal undergoes a superconducting transition. The electronic contribution, however, which is proportional to temperature for a normal metal, $C_e^{(n)}(T) \propto T$, is found to vanish exponentially in the superconducting state: $C_e^{(s)}(T) \propto \exp(-\Delta/k_BT)$ (see Fig. 7). Such a dependence is characteristic for systems with an energy gap. The measurement of the normal-state specific heat can be performed after application of an external magnetic field that is larger than the critical field.

1.5.2 Electromagnetic and Acoustic Absorption As is the case in other materials with an energy gap, such as insulators and semiconductors, in superconductors the gap manifests itself in the optical absorption spectra as an absorption edge at the frequency $\omega = 2\Delta/\hbar$ since the photon energy has to exceed the energy 2Δ necessary to break up a Cooper pair. These frequencies are of the order of 10^{10}–10^{12} Hz (far infrared), which corresponds to the frequency interval where the ac electrical resistance becomes finite (see Sec. 1.1).

The energy of the low-frequency ultrasonic phonons employed in ultrasonic attenuation experiments is too small to break up the Cooper pairs; instead, these phonons couple to low-energy excitations already present, the number of which is proportional to $\exp(-\Delta/k_BT)$. The ratio of the ultrasonic attenuation coefficients α in the superconducting and normal states, respectively, is given by

$$\frac{\alpha_s}{\alpha_n} = \frac{2}{\exp(\Delta/k_BT) + 1}.$$

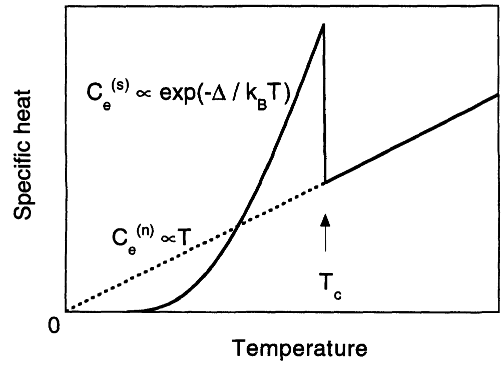

FIG. 7. Temperature dependence of the low-temperature electronic specific heat $C_e(T)$ for a metal in the normal (dotted line) and superconducting (solid curve) states. In the normal state, the electronic contribution to the specific heat is proportional to temperature, $C_e^{(n)} \propto T$, whereas the electronic specific heat vanishes exponentially in the superconducting state: $C_e^{(s)} \propto \exp(-\Delta/k_BT)$. The lattice contribution to the specific heat is negligible at low temperatures.

Measurements of the ultrasonic attenuation have confirmed the predictions of the BCS theory (see Sec. 2.1) for the temperature dependence of the energy gap and its correlation with the critical temperature.

Low-frequency electromagnetic absorption is probed by nuclear magnetic resonance (NMR) experiments that determine the spin–lattice relaxation rate T_1^{-1}. In analogy to the ultrasonic attenuation experiments, only scattering of quasiparticles can contribute to the scattering for $h\nu \ll \Delta(T)$, where ν is the precession frequency of the nuclear spins. Thus, for $T \ll T_c$, T_1^{-1} decreases exponentially with decreasing temperature. (For temperatures slightly below T_c, the relaxation rate increases, which is predicted correctly by the BCS theory.)

1.5.3 Electron Tunneling When a normal metal and a superconductor are separated by a thin insulating barrier (for instance, an oxide layer with a thickness of a few nanometers), electrons can cross this barrier by the quantum mechanical tunnel effect. If the electrons are bound in Cooper pairs with a binding energy of 2Δ per pair, an energy Δ has to be supplied to cause an electron to break free and traverse the barrier. This becomes apparent in the current–voltage (I-V) characteristics that are illustrated in Fig. 8. When the superconductor is in the normal state, $I \propto V$ (Ohmic behavior). In the superconducting state, on the other hand, essentially no current flows until the voltage reaches the value $V = \Delta/e$ (for $T = 0$, the current is zero; at finite temperatures, there are always individual electrons that are not condensed into Cooper pairs and can tunnel under the influence of an arbitrarily small potential difference, thus giving rise to a background current). The gap is preferably estimated from the maximum in the differential conductivity dI/dV.

1.6 Josephson Effects

Two superconductors separated by a thin region in which the Cooper-pair density is locally reduced form a weak link or Josephson junction. It can be realized either as a tunnel junction, where an insulating or nor-

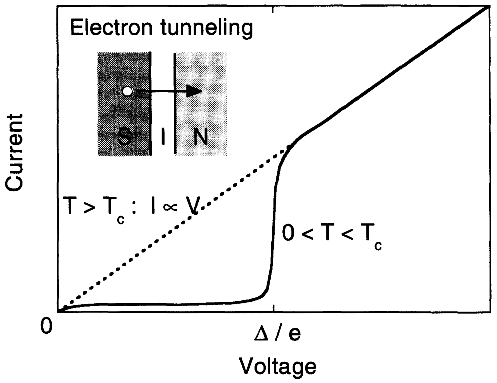

FIG. 8. Current–voltage (*I*-*V*) characteristics of a superconductor–insulator–normal metal (SIN) tunnel junction. With the superconductor in the normal state, the junction exhibits Ohmic behavior, $I \propto V$, whereas in the superconducting state, a voltage of the order of Δ/e is necessary to excite an electron across the energy gap.

mal conducting layer with a thickness of typically less than 20 Å is sandwiched between superconductors, as a point-contact junction between a flat superconducting surface and a superconducting tip, or as a bridge junction in the form of a thin constriction within a superconductor. In addition to the single-electron tunneling current (see Sec. 1.5.3) flowing across a Josephson junction, there may be a supercurrent of Cooper pairs traversing the barrier.

This phenomenon is known as the dc Josephson effect. In the absence of a magnetic field, the current density j_J associated with the Josephson current is determined by the phase difference $\Delta\phi$ of the macroscopic superconducting wave functions of the two superconductors:

$$j_\mathrm{J} = j_c \sin \Delta\phi,$$

where j_c is the critical current density of the junction, which depends on the value of the energy gap of the superconductors and on the normal-state resistivity of the weak link. Its value is much smaller than the typical bulk critical current density.

The Josephson current density j_J exhibits a dramatic dependence on the magnetic field through the junction, varying sinusoidally along the coordinate perpendicular to the field. The magnetic-field (or rather magnetic-flux) dependence of the maximum average current density j_max across the entire junction is given by

$$j_\mathrm{max} = j_c \left| \frac{\sin(\pi\Phi/\Phi_0)}{\pi\Phi/\Phi_0} \right|,$$

which implies that the Josephson current vanishes whenever the external field corresponds to a magnetic flux Φ through the junction that is equal to an integer number of flux quanta, $n\Phi_0$. This field dependence is the basis of the importance of Josephson junctions for magnetic-field–sensing applications (see Sec. 4.2).

If a constant electric potential difference is present across the weak link (e.g., through the application of a dc voltage V, or because the current passing through the junction is higher than the critical current), an oscillating supercurrent will appear,

$$j(t) = j_c \sin\left(\Delta\Phi_0 + \frac{2eV}{\hbar} t\right),$$

where the Josephson frequency $\omega_\mathrm{J} = 2eV/\hbar$ of this alternating current is of the order of 10^{11} Hz for voltages in the millivolt range. This phenomenon is referred to as the ac Josephson effect. If a junction biased with a constant current to a voltage V is subjected to microwave irradiation of frequency ω_0, the oscillating supercurrent contains a stationary component whenever $\omega_\mathrm{J} = n\omega_0$. This leads to the appearance of constant-voltage steps in the *I*-*V* characteristics of the junction at finite voltage values $V_n = n\omega_0\hbar/2e$. These features are known as Shapiro steps. Applications of the ac Josephson effect are described in Sec. 4.2.

1.7 Isotope Effect

The attractive electron interaction that leads to the formation of Cooper pairs is mediated by exchange of virtual lattice vibrations or phonons (see Sec. 2.1.2). The superconducting properties are, therefore, influenced by changes in the masses of the constituents of the crystal lattice. This becomes apparent in the variations of the transition temperature T_c when one isotope of a superconducting element is replaced by another isotope:

$$T_c \propto M^{-\alpha},$$

where M is the atomic weight and $\alpha = \frac{1}{2}$. This expression describes the so-called isotope effect. It has been verified experimentally for a variety of materials. Deviations of the value of α from $\frac{1}{2}$ can be explained by modifications of the BCS theory taking into account electron–electron Coulomb interaction.

2. THEORY OF SUPERCONDUCTIVITY

2.1 BCS Theory

The microscopic theory of superconductivity was developed by J. Bardeen, L. N. Cooper and J. R. Schrieffer and is known as the BCS theory.

2.1.1 Cooper Pairs In the BCS theory, it was shown that the Fermi-sea ground state is, in the presence of a weak attractive interaction between the electrons, unstable with respect to the formation of bound pairs of electrons occupying states with equal and opposite momentum and spin; i.e. $(\mathbf{k}\uparrow; -\mathbf{k}\downarrow)$. The spatial extent of the superconducting electron pairs, commonly referred to as Cooper pairs, determines the superconducting coherence length $\xi \approx hv_F/k_BT_c$, where v_F is the Fermi velocity. According to the theory, the binding energy, which corresponds to the minimum energy required to break a pair, creating two quasiparticle excitations, is given by $E_g(T) = 2\Delta(T)$, where $\Delta(T)$ is the temperature-dependent energy gap in the quasiparticle excitation spectrum. The plot of the energy gap as a function of temperature in Fig. 9 illustrates that Δ vanishes at T_c and achieves its maximum value $\Delta(0) = 1.764k_BT_c$ at $T = 0$. The energy gap is manifested in various physical properties such as electron-tunneling spectra, ultrasonic attenuation, nuclear relaxation, electromagnetic absorption, and specific heat (see Sec. 1.5).

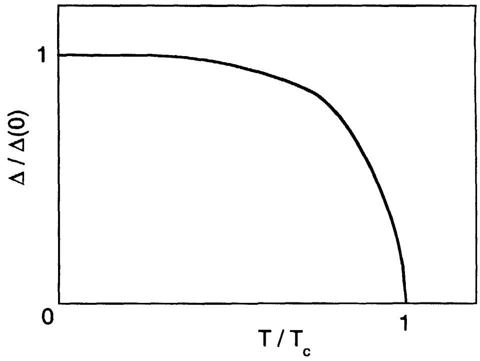

FIG. 9. Temperature dependence of the energy gap $\Delta(T)$ as given by the BCS theory.

2.1.2 Electron-Pairing Mechanism In conventional superconductors, the weak attractive interaction that binds the two electrons of a Cooper pair together, overcoming the strong Coulomb repulsion between them, is mediated by the exchange of virtual quantized lattice vibrations or phonons, which ordinarily scatter the electrons in the normal state. The way the attractive electron–phonon interaction works can be visualized in the following way: A negatively charged conduction electron passing in the vicinity of a positively charged ion exerts an attractive force on the ion and displaces it from its equilibrium lattice position, producing a local net positive charge that attracts a second negatively charged electron traveling through that region. This results in a weak attractive interaction between the two electrons that can overcome the Coulomb repulsion because the electrons move much faster than the ions (i.e., the lattice distortion persists for a relatively long time compared to the transit time of the electron that produced it).

The BCS theory successfully accounts for the properties of the conventional superconductors and provides an expression for the transition temperature T_c in terms of the properties of the normal state, given by

$$T_c \approx \Theta_D \exp\left[\frac{1}{\mathcal{N}(E_F)\mathcal{V}}\right],$$

where Θ_D is the Debye temperature, $\mathcal{N}(E_F)$ is the density of electronic states at the Fermi level E_F, and $\mathcal{V}$ is the strength of the attractive electron–phonon interaction. Since $\Theta_D \propto M^{-1/2}$ for a monatomic lattice of atoms of mass M, it follows that $T_c \propto M^{-\alpha}$ with $\alpha = \frac{1}{2}$, which provides an explanation for the isotope effect (see Sec. 1.7). This expression also accounts for the minimum in T_c observed for the transition-metal superconductors near the half-filled d-electron shell where $\mathcal{N}(E_F)$ passes through a minimum. Refinements of the BCS theory that include the effect of the Coulomb repulsion between the electrons are capable of accounting for the reduced values of α found for transition-metal element superconductors (e.g., $\alpha = 0.37$ for Mo, 0.38 for Re, and 0.21 for Os, and ~0 for Ru and Zr). An approach that has achieved some success in accounting for the values of T_c and the isotope-effect exponent α for transition-metal elements and alloys, which are in the strong-coupling limit $T_c/\Theta_D \gtrsim 0.05$, is due to McMillan. The McMillan theory gives the following approximate expressions for T_c and α:

$$T_c = \frac{\Theta_D}{1.45}\exp\left[-\frac{1.04(1+\lambda)}{\lambda - \mu^*(1+0.62\lambda)}\right]$$

and

$$\alpha = \tfrac{1}{2}\left[1 - \left(\mu^* \ln\frac{\langle\Omega\rangle}{1.2T_c}\right)^2 \frac{1+0.62\lambda}{1+\lambda}\right],$$

where λ is an electron–phonon interaction parameter that ranges from 0.1 to 1.5 in various metals, μ^* is a Coulomb repulsion parameter that is often found to be ~0.1, and $\langle\Omega\rangle$ is an average phonon frequency defined by

$$\langle\Omega\rangle = \frac{\int \alpha^2(\Omega)d\Omega}{\int \alpha^2(\Omega)F(\Omega)d\Omega/\Omega},$$

where $\alpha^2(\Omega)$ is the effective electron–phonon coupling constant and $F(\Omega)$ is the phonon density of states, which can be extracted from quasiparticle tunneling spectra and inelastic neutron-scattering experiments. The electron–phonon interaction enhances $\mathcal{N}(E_F)$ or the electron mass m^* with respect to their bare values $\mathcal{N}_0(E_F)$ and m by $\mathcal{N}(E_F)/\mathcal{N}_0(E_F) = m^*/m = 1 + \lambda$.

2.2 Ginzburg–Landau Theory

Prior to the publication of the BCS theory, V. L. Ginzburg and L. D. Landau (GL) developed a phenomenological theory based on a pseudo wave function Ψ that serves as a complex order parameter such that $|\Psi(\mathbf{r})|^2$ represents the local density of superconducting electrons $n_s(\mathbf{r})$. The wave function can be viewed as the wave function of the center of mass of the Cooper pairs. The theory is capable of treating situations in which n_s varies in space and where a nonlinear field response is strong enough to change n_s. Predictions of critical fields and of the spatial structure of $\Psi(\mathbf{r})$ in nonuniform situations have been made based on the GL theory. The wave function Ψ satisfies a differential equation that is analogous to the Schrödinger equation for a free particle, but with a nonlinear term, and is given by

$$\frac{1}{2m^*}\left(\frac{\hbar}{i}\nabla - \frac{e^*}{c}\mathbf{A}\right)^2 \Psi + \beta|\Psi|^2\Psi = -\alpha(T)\Psi.$$

The equation for the supercurrent,

$$\mathbf{J}_s = \frac{e^*\hbar}{i2m^*}(\Psi^*\nabla\Psi - \Psi\nabla\Psi^*) - \frac{e^{*2}}{m^*c}|\Psi|^2\mathbf{A},$$

is the same as the quantum-mechanical expression for a particle of charge e^* and mass m^*. For a superconductor, the relevant particle is a Cooper pair for which $e^* = 2e$ and $m^* = 2m$. One of the parameters that emerges from the GL theory is the temperature-dependent superconducting coherence length

$$\xi(T) = \hbar/|2m^*\alpha(T)|^{1/2},$$

which characterizes the distance over which $\Psi(\mathbf{r})$ can vary without appreciable energy change. L. P. Gor'kov showed that the phenomenological theory is a limiting form of the microscopic BCS theory (suitably generalized to deal with situations where n_s is varying in space), which is valid near T_c, and in which Ψ is directly proportional to the gap parameter Δ.

Near T_c, $\xi(T)$ diverges as $(T - T_c)^{-1/2}$, and α vanishes as $T - T_c$. The temperature-dependent GL coherence length ξ and penetration depth λ in the clean ($\xi_0 \gg l$) and dirty ($\xi_0 \ll l$) limits, respectively, can be expressed in terms of the BCS coherence length $\xi_0 = \hbar v_F/\pi\Delta(0)$ and the transport mean free path l:

$$\xi_{\text{clean}} = 0.74\xi_0(1 - T/T_c)^{-1/2},$$

$$\lambda_{\text{clean}} = \lambda_L(0)[2(1 - T/T_c)]^{-1/2},$$

$$\xi_{\text{dirty}} = 0.85(\xi_0 l)^{1/2}(1 - T/T_c)^{-1/2},$$

$$\lambda_{\text{dirty}} = 0.615\lambda_L(0)(\xi_0/l)^{1/2}(1 - T/T_c)^{-1/2},$$

where $\lambda_L(0) = (mc^2/4\pi|\Psi|^2e^2)^{1/2}$.

The Ginzburg–Landau parameter $\kappa = \lambda/\xi$ determines the sign of the surface energy associated with an interface between superconducting and normal material, thus distinguishing between type I and type II superconductors (see Sec. 1.3.3.1). The GL theory is capable of describing both the intermediate state for type I materials ($\kappa \ll 1$), where a domain pattern is stabilized by the positive surface energy associated with the domain walls (see Sec. 1.3.2), and the mixed state in type II systems ($\kappa \gg 1$), where the negative surface energy gives rise to flux penetration in the form of fluxoids. It is applicable to many situations including the calculation of the bulk critical fields H_{c1} and H_{c2} and the surface critical field H_{c3}, the structure of an isolated vortex and of the vortex lattice (Abrikosov vortex lattice), and superconducting fluctuations. It has been very useful in treating the properties of ferromagnets, as well as the interaction between superconductivity and magnetic order.

3. SUPERCONDUCTING MATERIALS

3.1 Elements

Most of the metallic elements that do not exhibit magnetic order become superconducting when cooled to a sufficiently low temperature. The element Nb has the highest transition temperature T_c at atmospheric pressure ($T_c = 9.3$ K), while La has the highest T_c when subjected to high pressure ($T_c =$ 11.2 K at 16 GPa compared to ~6 K at atmospheric pressure). Many of the metallic elements have been tested for superconductivity down to temperatures as low as ~1 mK and at high pressures of several tens of gigapascals and higher. Table 1 lists the transition temperatures of some of the superconducting elements. Shown in Fig. 10 is a periodic table of the elements in which the known superconducting elements are marked.

The critical temperatures of the transition-metal elements exhibit a characteristic variation with the valence-electron concentration (vec) that is characterized by pronounced maxima near vec values of 5 and 8, respectively. Here, the vec is the number of outermost electrons, including those in the d shell and the s and p shells. This characteristic dependence of T_c on the vec of the transition-metal elements and of alloys formed between neighboring elements in the periodic table is part of "Matthias's rules," named after the late pioneer in superconducting materials, B. T. Matthias. It is illustrated in Fig. 11.

Table 1. Superconducting transition temperature T_c of some elements. The greek letters indicate different modifications for polymorphic elements; the corresponding crystal structure is indicated.

Element	T_c (K)	Structure
Nb	9.2	Cubic
Pb	7.2	Cubic
La (α)	6.0	Cubic
V	5.3	Cubic
La (β)	4.9	Hexagonal
Ta	4.6	Cubic
Hg (α)	4.2	Rhombohedral
Hg (β)	4.0	Tetragonal
Sn (β)	3.7	Tetragonal
In	3.4	Tetragonal
Tl	2.4	Cubic
Re	1.7	Hexagonal
Th (α)	1.4	Cubic
Al	1.2	Cubic
Ga	1.1	Orthorhombic
Mo	0.92	Cubic
Zn	0.87	Hexagonal
Os	0.66	Hexagonal
Cd	0.54	Hexagonal
Ru	0.49	Hexagonal
Ti (α)	0.39	Hexagonal
Ir	0.10	Cubic
W	0.012	Cubic

Some elements, such as Be, Bi, and Ga, become superconducting only in the form of thin films after being vacuum deposited at temperatures below ~10 K ("collapsed" phases). After a temperature increase, they undergo an irreversible transition into a nonsuperconducting phase.

3.2 Binary Alloys, *A*15 Compounds

Many of the compounds formed by alloying transition-metal elements and other metallic elements exhibit variations in T_c with the vec that conforms to Matthias's rule. One particularly important group included in this category consists of the *A*15 compounds, the materials that exhibited the highest values of T_c prior to the discovery of layered high-T_c cuprate compounds. The *A*15 materials are

described by the general chemical formula A_3B, where A is Nb or V and B is a non-transition-metal element such as Al, Ge, Ga, Sn, or Bi; they crystallize in a cubic crystal structure. The unit cell consists of a non-transition-metal element in a body-centered cubic lattice with the Nb or V atoms forming nonintersecting chains closely spaced on each cubic face as shown in Fig. 12.

Table 2 gives T_c values for some $A15$ compounds. Many of the materials belonging to this group exhibit very high upper critical fields H_{c2}, which can reach values in the range of 2×10^7 A m^{-1} (240 kOe) for Nb_3Sn

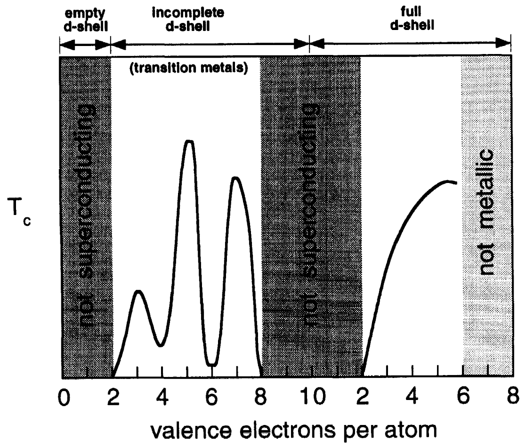

FIG. 11. Matthias's empirical rule for the superconducting transition temperature T_c throughout the periodic system.

to 3×10^7 A m^{-1} (380 kOe) for Nb_3Ge. This is the basis for the application of some *A*15 compounds in the fabrication of wires for the production of superconducting electromagnets and in other applications of superconductivity (see Sec. 4.1). Other superconducting materials with relatively high T_c's that are currently used in technological applications include Nb-Ti and Nb-Zr alloys, which have T_c values of ~12 K. Another interesting compound with $T_c \sim 15$ K is NbN, which has the *B*-1 (NaCl) structure. A large number of superconductors crystallize in this structure. The superconductivity in these materials is rather resistive to disorder, in contrast to the *A*15 compounds whose superconducting properties are very sensitive to disorder. A particularly interesting *B*-1 superconductor is PdH, which can be synthesized by low-temperature ion implantation. The T_c of this material reaches 17 K when it is alloyed with Ag.

3.3 Ternary Compounds

An important class of ternary compounds has crystal structures that consist of molecular units or clusters of atoms within which the superconducting charge carriers are confined. This produces large values of the electronic density of states at the Fermi level, which apparently contributes to the relatively high T_c values of these materials. Two of the best known examples are the Chevrel-phase compounds MMo_6X_8, where *M* is one of many metals and *X* is a chalcogenide, and the rare-earth (*R*) rhodium borides RRh_4B_4. The highest T_c value for the former materials is ~15 K for $PbMo_6S_8$ and, for the latter compounds, ~11 K for YRh_4B_4. In these materials, the atomic clusters are Mo_6X_8 or Rh_4B_4 molecular units. The compound $PbMo_6S_8$ is the low-T_c superconductor with the highest H_{c2}, which reaches about 7×10^7 A m^{-1} (620 kOe) for $T \to 0$.

3.4 Magnetically Ordered Superconductors

Magnetically ordered superconductors are materials in which superconductivity and magnetic order occur within the chemical unit cell of the material. Two classes of *f*-electron materials fall into this category: molecular compounds and heavy-fermion compounds. In the molecular compounds, the electrons involved in the superconductivity reside primarily within the molecular units and interact only weakly with the magnetic moments of the rare-earth ions with partially filled 4*f* electron shells that occupy an ordered sublattice.

Antiferromagnetic order has been found to coexist with superconductivity in many materials, while ferromagnetic order has been observed to destroy superconductivity at a temperature T_{c2} near the Curie temperature and to produce a sinusoidally modulated magnetic state that coexists with superconductivity in a narrow temperature interval above T_{c2}. The materials in which these phenomena were first discovered include the rare-earth (*R*) molybdenum chalcogenides RMo_6X_8 (X = S, Se) and the rare-earth rhodium borides RRh_4B_4.

3.5 Heavy-Fermion Superconductors

Certain rare-earth and actinide intermetallic materials, known as heavy-fermion compounds, have effective electron masses of several hundred times the free electron mass, due to hybridization between the conduction electron states and the localized *f*-electron states (see HEAVY-FERMION PHENOMENA). A small number of Ce and U heavy-fermion compounds such as $CeCu_2Si_2$, UBe_{13}, UPt_3, URu_2Si_2, and UPd_2Al_3 exhibit superconducting behavior with values of T_c below ~2 K. The superconductivity in these materials appears to involve an energy gap that vanishes at points or along lines on the Fermi surface. The mechanism responsible for the pairing of the superconducting charge carriers may be mediated by magnetic excitations, rather than phonons. Several of the heavy-fermion compounds exhibit the coexistence of superconductivity and antiferromagnetism where both phenomena involve the same set of *f* electrons.

3.6 Low-Electron-Density Superconductors

This class of superconductors consists of materials with a low electronic density of states compared to the metallic systems described thus far. Among these compounds are several tellurides such as GeTe, SnTe, InTe, and Tl-doped PbTe. Another prominent group of materials includes superconducting oxides, in particular $SrTiO_3$ and $Ba(Bi_{1-x}Pb_x)O_3$, with the latter compound exhibiting a relatively high transition temperature of $T_c = 13$ K. In general, the transition temperature increases with increasing number density of the charge carriers. It is interesting to note that for $SrTiO_3$, T_c decreases after an initial increase when the carrier density is enhanced by doping. The decrease has been attributed either to screening of optical modes involved in the pairing by conduction electrons or to paramagnetic defects introduced with the doping.

3.7 Low-Dimensional Superconductors

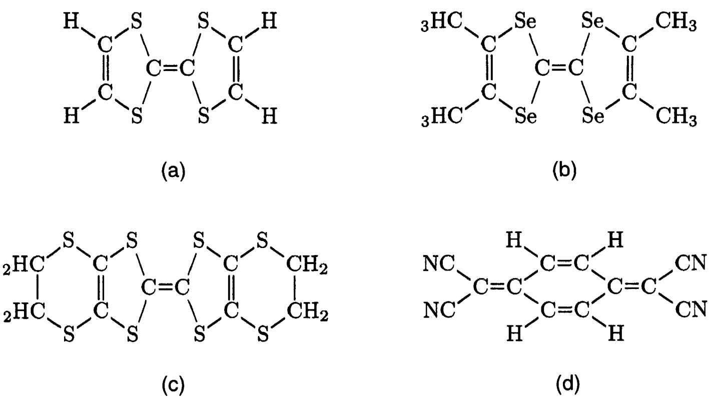
Systems with pronounced structural and electronic anisotropies resulting in an effective reduced dimensionality have been of great interest, since superconducting electron pairing mechanisms mediated by excitations different from phonons have been suggested to be relevant in these cases, with a high dielectric polarizability giving rise to the attractive electron interaction and possibly to very high T_c. Furthermore, the occurrence of spin- and charge-density waves and of superconductivity as a result of the instability of the Fermi surface in low-dimensional systems and the competition between these interaction effects have attracted a lot of interest. Charge-density waves were first observed in superconducting layered transition-metal dichalcogenides, such as $NbSe_2$ or TaS_2. By intercalation of various amides and amines into TaS_2, the charge-density wave can be suppressed, resulting in an increase in T_c. Some of these and other intercalated compounds, such as MoS_2 intercalated with alkali-metal and alkaline-earth elements, exhibit very high initial upper critical field slopes close to T_c.

Other examples of low-dimensional materials exhibiting superconducting behavior include quasipolymeric strands of sulfur and nitrogen $(SN)_x$, organic charge-transfer salts (see Sec. 3.8), graphite intercalation compounds (see Sec. 3.9), and the high-T_c cuprates.

3.8 Organic Superconductors

A variety of organic compounds conducts electricity, the most prominent group being the so-called charge-transfer salts that contain donor (cation) and acceptor (anion) molecules (see SEMICONDUCTORS TO SUPERCONDUCTORS: ORGANIC LOWER-DIMENSIONAL SYSTEMS). Figure 13 shows several examples of donor and acceptor groups and gives the common abbreviations.

The conducting properties arise from the charge delocalization due to the strong overlap of π orbitals achieved by stacking the mostly planar molecules on top of each other. This layered structure gives rise to a pronounced anisotropy in the conductivity.



(a) (b) (c) (d)

FIG. 13. Typical donor and acceptor molecules forming organic charge-transfer conductors. (a) Tetrathiafulvalene (TTF). (b) Tetramethyltetraselenafulvalene (TMTSF). (c) Bis(ethylenedithia)-tetrathiafulvalene (BEDT-TTF or ET). (d) Tetracyanoquinodimethane (TCNQ). (a)–(c) are donors; (d) is an acceptor.

In 1980, the first organic superconductor, $(TMTSF)_2PF_6$, was discovered, with a T_c of 0.9 K at a pressure of 1.2 GPa (12 kbar). This material is a member of the family of compounds with the general formula $(TMTSF)_2X$ known as Bechgaard salts, where X is an inorganic anion such as PF_6^-, AsF_6^-, ReO_4^-, or ClO_4^-. The highest T_c achieved in this class is about 2 K.

Another important group of organic superconductors is based on the BEDT-TTF (ET) molecule (see Fig. 13) and described by the general formula $(ET)_2X$. The first superconducting compound of this class, $(ET)_2ReO_4$, was discovered in 1983. It has a T_c of about 2 K. Subsequently, higher transition temperatures of up to 12 K (at ambient pressure) were observed in compounds with X = $Cu(SCN)_2^-$, $Cu[N(CN)_2]Br^-$, and $Cu[N(CN)_2]Cl^-$.

Because of the strongly anisotropic character of the conductivity, organic superconductors are considered examples of "reduced dimensionality" systems. They exhibit very rich phase diagrams characterized by ground states where charge- and spin-density modulations are competing with superconductivity.

3.9 Carbon-Based Superconductors

Various graphite intercalation compounds (see INTERCALATION COMPOUNDS), which are formed by the insertion of atomic or molecular layers (intercalants) between the layers of graphite, exhibit superconductivity. Examples for these materials, which are often characterized by strongly anisotropic, quasi two-dimensional superconducting properties, include C_4KHg, C_4RbHg, C_8KHg, C_8RbHg, and C_8K, with T_c ranging from 150 mK to 19 K. Surprisingly, the critical temperatures of the C_8XHg compounds (X = K, Rb), where the intercalant sheets are separated by two graphite layers (two-staged), are higher than those for the one-staged C_4XHg materials.

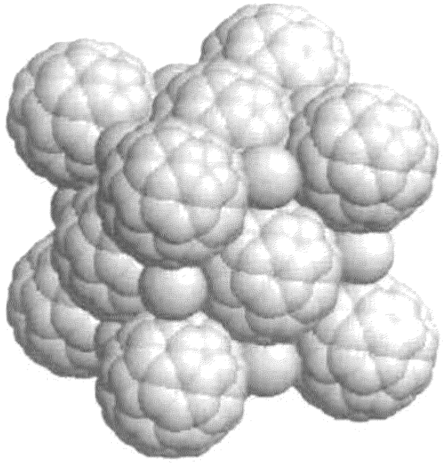


FIG. 14. Structure of the superconducting alkali-metal fulleride A_3C_{60}. The C_{60} molecules form a fcc lattice, with the smaller A cations occupying tetrahedral and octahedral sites.

Another fascinating group of superconductors that was discovered in 1991 is based on the intercalation of alkali-metal atoms into the interstitial sites of a spherically close-packed, face-centered cubic (fcc) solid of C_{60} molecules (see Fig. 14). C_{60} is a member of the fullerene family of carbon compounds forming soccer-ball–shaped molecules of high symmetry (see FULLERENES). If each of the two tetrahedral and the one octahedral sites per C_{60} unit are occupied by a single alkali-metal atom A, the resulting compound can be described by the general chemical formula A_3C_{60}. For higher alkali-metal concentrations, the crystal expands and undergoes a structural phase transition into body-centered tetragonal and body-centered cubic structures. The superconducting transition temperature T_c increases nearly linearly with increasing lattice constant a, and the application of hydrostatic pressure causes a contraction of the lattice and an associated suppression of T_c. While K_3C_{60}, the first superconducting fullerene to be discovered, exhibits a T_c of 18 K, a maximum T_c of 33 K was reported for the compound $RbCs_2C_{60}$. The observation of a distinct isotope effect (see Sec. 1.7) suggests phonon-mediated pairing of electrons as described by the BCS theory (see Sec. 2.1) as the mechanism responsible for superconductivity in these compounds, although pairing based on electron–electron correlations has also been considered.

4. APPLICATIONS OF SUPERCONDUCTIVITY

The large variety of physical phenomena associated with superconductivity are the basis of many applications involving superconducting materials and/or devices.

4.1 Large-Scale Applications

The capability of "hard" type II superconductors to carry large electrical currents in the presence of high magnetic fields naturally suggests their application for cables and conductors and in devices based on such conductors.

4.1.1 Superconducting Wires Wires based on superconducting materials that are to be used in conductors for energy or magnet technology have to meet a variety of requirements (see SUPERCONDUCTING MAGNETS): The transition temperature T_c, upper critical field H_{c2}, and critical current density j_c of the superconducting material should be as high as possible. The conductor should be stable against thermal fluctuations and flux jumps and tolerate sudden breakdown of superconductivity ("quenching"). The ac losses associated with changes in current and/or fields—e.g., during charging and discharging or pulsed operation of magnets, or in ac power applications—should be minimized. The mechanical properties should allow realization of complex conductor geometries (especially magnet coils) and, at the same time, provide sufficient strength to withstand the immense magnetic forces that may be present during operation.

Only two superconducting materials exhibit high enough critical current densities at elevated fields to be technologically relevant *and* have also been successfully integrated into the manufacturing process: the ductile alloy Nb-Ti and the brittle *A*15 compound Nb_3Sn. Because of its much more difficult processing, Nb_3Sn is only used at fields above $\sim 8 \times 10^6$ A m^{-1} (100 kOe), where the critical current density of Nb-Ti drops very rapidly with increasing field.

The conductors are produced in the form of composite wires consisting of up to 100 000 superconducting filaments that are embedded within a ductile, metallic matrix (usually copper). This subdivision into filaments with diameters ranging from ~ 1 to ~ 100 μm helps to suppress magnetic instabilities. Furthermore, the increased surface area between the superconducting filament material with its very low thermal conductivity and the Cu matrix, which is an excellent thermal conductor, provides more efficient cooling and increased thermal stability. In addition, the low-resistivity Cu matrix can carry the current in the event of a breakdown of superconductivity without developing dangerously large amounts of Joule heating. Finally, the matrix provides additional mechanical stability.

A typical manufacturing process for Nb-Ti wires includes the bundling of the superconducting and metallic components into a billet, followed by warm extrusion and drawing. In the case of the brittle Nb_3Sn, a "wind-and-react" technique is employed, where ductile composites consisting of Cu, Nb, and Sn are fabricated, whereas the superconducting phase is formed by solid-state reaction only after the conductor is given its final geometry. The filament diameter has to be limited to a few microns in order to facilitate the formation of Nb_3Sn within a reasonable time span. Thus, a high number of filaments are required, which can be achieved by repeating the bundling and drawing process.

Usually, the strands of multifilamentary wire are twisted to reduce ac losses, to limit the coupling between currents in neighboring filaments, and to increase magnetic stability. Figure 15 shows a cross-sectional image of a Nb-Ti multifilamentary wire. For applications requiring very large fields, additional stabilizing material (Cu, Al), mechanical reinforcements, and cooling channels for

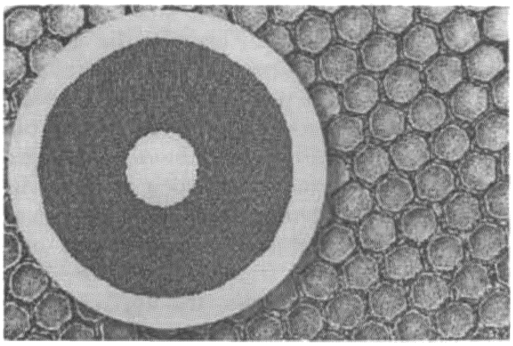

FIG. 15. Multifilamentary superconducting composite strand produced by IGC Advanced Superconductors for the SSC (superconducting supercollider) project. The strand (inset) is composed of a high-purity Cu stabilizing matrix and a single stack of over 4000 Nb–47 wt.% Ti filaments. Each Nb–Ti filament is wrapped in a Nb diffusion barrier (detail). Under thermomechanical processing, a fine dispersion of α-Ti precipitates is produced in the Nb–Ti, which are the primary flux pinners. (Micrograph by P. J. Lee. Reproduced with permission.)

the cryogens may be required. In ac applications, the Cu matrix may be subdivided by CuNi barriers to reduce eddy-current losses. Current-carrying capacities of more than 1 kA in fields up to $\sim 2 \times 10^7$ A m^{-1} (>200 kOe) can be achieved.

4.1.2 Superconducting Magnets By far, the most widespread application of conductors based on superconducting materials is in electromagnets. Superconducting magnets offer a number of advantages in comparison to conventional electromagnets made from normal metals: As a result of the absent (or very low) losses due to Joule heating, very high currents can be passed through the superconducting magnet windings, creating magnetic fields that are hardly achievable with conventional magnets. The lower losses drastically reduce the amount of electrical energy required to produce and maintain the magnetic fields. Superconducting magnets are much more compact and lightweight than conventional magnets that generate comparable fields. Since many applications require the magnetic field to be constant as a function of time, superconducting magnets are very often operated in the so-called persistent mode: The magnet terminals are shunted by a superconducting bridge (usually Nb-Ti) that can be driven normal by a heater wound coaxially around it. This assembly is referred to as a persistent switch. When the heater is activated and the switch is normal ("open"), the current flowing through the magnet may be changed using a connected power supply to generate the desired field. After turning the heater off, the persistent switch cools down, creating a superconducting loop consisting of the magnet windings and the switch. The persistent current that circulates in this circuit produces the extremely stable magnetic field.

Here, we only mention the application of superconducting magnets as laboratory research magnets, for nuclear magnetic resonance (NMR) spectrometers and magnetic resonance imaging (MRI); for particle acceleration, guidance, and detection; for plasma confinement in thermonuclear fusion reactors; and for magnetic levitation (see TRANSPORT BY MAGNETIC LEVITATION), magnetic separation of materials, or superconducting magnet energy storage (SMES) (see STORAGE OF ENERGY). For more details about superconducting magnets we refer the reader to the corresponding article.

4.1.3 Motors and Generators Superconducting generators and motors are considerably more efficient and lighter than their normal conducting counterparts. Both 5- and 10-MVA superconducting generators have been successfully tested; however, the breakeven point for economical usage is estimated to be reached only at 500–600 MVA. Combinations of superconducting generators, driven by gas turbines, with superconducting motors powered by the generators have been considered for ship propulsion, and a 3000-HP (2250-kW) system using a homopolar motor has been successfully tested by the U.S. Navy.

4.1.4 Electrical Power Transmission and Distribution Because of the vanishing dc losses and (for low ac field amplitudes) low 50/60-Hz losses, the transmission efficiency of superconducting power cables is much higher than for conventional cables. The feasibility and performance of metallic 4-K superconducting cables with lengths of up to 115 m has been demonstrated. However, the economic breakeven point would only be reached at transmission rates of 4000–5000 MVA, which is far beyond the values achieved in the tests.

Another potential application of superconductors in power networks is the superconducting fault-current limiter, which, in the case of a short-circuit, would enter the resistive normal state, thereby effectively limiting the current. Such a limitation would prevent damages to network components and reduce the load on generators, transformers, and switches. The lack of mechanically actuated parts should improve the reliability of the current limiter. Prototype single-phase current limiters consisting of Nb-Ti filaments embedded in highly resistive Cu-Ni have been successfully tested. As in the case of the cables, however, the high investment and operating costs have prevented large-scale implementation.

Transformers with superconducting windings also offer lower ac losses, higher efficiency, and a drastic reduction of size and weight, compared to normal conducting components. At the same time, the short-circuit current is limited to about double the normal operating current, which reduces the forces in the windings and thus allows simplification of the mechanical construction. However, care has to be taken to avoid eddy-current losses in the metallic matrix. While prototypes of 220-kV transformers constructed using submicron Nb-Ti wires embedded in Cu-Ni have been successfully tested, the efficiency did not surpass that of comparable conventional systems because of high thermal losses at the current feedthroughs. Nevertheless, the fault-current limiting capability of the superconducting windings was demonstrated, and a tenfold reduction in mass was achieved.

The application of low-T_c superconductors in electrical power transmission and distribution networks requires a further improvement in their superconducting properties, since only very large-scale units can be operated economically.

4.2 Small-Scale Applications

In contrast to the applications discussed above, the devices and techniques of this group are characterized by much smaller currents. They are mostly based on the Josephson effects (see Sec. 1.6) and are typically realized using thin-film technology.

4.2.1 Microwave Applications Passive high-frequency devices rely on the low surface resistance of superconductors, which enables them to transmit high-frequency signals with lower dissipation and less distortion than normal conductors, and allows reduction of the size of the elements. Among the devices realized are superconducting cavities and resonators, delay lines, filters, and antennas. Point-contact Josephson junctions, when biased to a steep part of a Shapiro step in their *I-V* characteristics (see Sec. 1.6), are very sensitive detectors of electromagnetic radiation in the microwave and submillimeter region. They can also function as efficient mixers.

4.2.2 Superconducting Quantum Interference Devices (SQUIDs) SQUIDs (*q.v.*) are the most sensitive detectors for magnetic flux. They are based on flux quantization and Josephson tunneling (see Sec. 1.6) and consist of a superconducting loop with one or more Josephson junctions.

With appropriate circuitry connected, SQUIDs can be used for the measurement of physical quantities that can be transformed into a magnetic flux, such as current, voltage, magnetic field gradient, magnetic susceptibility, or displacement. SQUIDs have been used to construct extremely sensitive voltmeters and galvanometers, as well as magnetometers in which the magnetic moments of very small samples can be determined with high accuracy. They are the basis of a primary thermometer measuring the Johnson noise of a resistor to determine temperature (see Sec. 4.2.4). Other applications include nondestructive evaluation of materials (see TESTING, NONDESTRUCTIVE), where SQUIDs measure the distortion of magnetic signals due to defects; geophysics (magnetotellurics, paleomagnetism, and piezomagnetics); and detectors for gravitational waves, where they are used to register the minute oscillations induced in large, freely suspended antennas by passing gravitational waves, as well as biomagnetism, i.e., the detection of the magnetic fields generated by the activity of biological systems, such as the human heart and brain (cardio- and neuromagnetism). For details of the principle, operation, and applications of SQUIDs, we refer the reader to the corresponding article.

4.2.3 Superconducting Digital Electronics The fact that Josephson junctions are capable of switching from the superconducting into the resistive state very rapidly (typical switching times are lower than 10 ps) makes Josephson-junction circuits very attractive for ultrahigh-speed digital signal processing. Other advantages are the integration of superconducting strip lines that are capable of transmitting terahertz signals without distorting them, and the very low power dissipation, which is of the order of a few microwatts and thus orders of magnitude lower than for semiconductor devices. Less power dissipation allows higher integration of the components, which reduces wiring delays. In addition, the quantization of magnetic flux in superconductors suggests the implementation of analog–digital converters and memory cells.

A variety of logic and memory circuits have been realized, initially based on lead-alloy technology; however, stability and reliability problems have induced increased efforts to produce integrated Josephson-junction circuits on the basis of other material combinations, such as NbN or Nb/Al/Al-oxide/Nb multilayers. Different types of logical gates have been proposed and realized: magnetic-coupled gates, where the state of Josephson junctions in a SQUID loop is switched by an external magnetic field associated with a current in a control line, and direct-coupled gates, in which the switching is triggered by injection of current directly into the circuit. Four- and eight-bit adders with subnanosecond addition times and (4 × 4)-bit multipliers containing more than 2800 individual Josephson junctions are among the logical circuits successfully tested, as well as four-bit counters, shift registers, and multiplexers. The realization of kilobit-sized random-access memory structures with subnanosecond access times is one of the main goals to be achieved in order to make progress on the way toward integrated superconducting digital systems.

4.2.4 Josephson-Junction Noise Thermometry Noise thermometers are based on the temperature proportionality of the Johnson-noise voltage fluctuations across a resistor. One implementation uses a Josephson junction that is biased by a dc current at a voltage V and is shunted by a resistor R ("R-SQUID"). The noise voltage across R modulates the high-frequency oscillation in the junction, and a measurement of the linewidth of this modulation, usually by detection of the frequency variance of the radiation emanating from the junction, yields the temperature information. In contrast to this absolute temperature measurement, which was used to establish a temperature scale between 6 and ~700 mK, an alternative method that uses a SQUID as an ultralow-noise preamplifier in a conventional noise thermometer circuit realizes a secondary thermometer that has to be calibrated against a primary standard.

4.2.5 Josephson-Junction Voltage Standard The presence of Shapiro steps in the I-V characteristics of Josephson junctions irradiated with microwaves of frequency ν_0 (see Sec. 1.6) provides a relationship between the voltage V_n, where the nth step is observed, and the frequency: $V_n = nh\nu_0/2e$. Since the frequency of the radiation can be stabilized to a very high degree, this opens up the possibility of using these steps to define reproducible reference voltages. A typical voltage value obtained using a single junction at a frequency of 70 GHz is 145 μV. For low microwave power, the constant-voltage steps overlap for a certain current bias, so that the voltage is multiple-valued with steps of $\Delta V = h\nu_0/2e$ between neighboring levels. All possible multiples of ΔV can be obtained in series arrays of Josephson junctions with appropriate combinations of the outputs of the individual junctions. Voltage standards up to the 10-V level have been achieved using series arrays of more than 10 000 individual junctions. Tuning the frequency of the microwave radiation allows the continuous change of the voltage, thus realizing a Josephson potentiometer. For details on the Josephson voltage standard, the reader is referred to the article CONSTANTS, FUNDAMENTAL. We only mention the use of superconductors as cryogenic current comparators, which are especially attractive for highly precise resistance-ratio measurements.

GLOSSARY

Abrikosov Vortex: Same as **Flux Line.**

Cooper Pair: Pair of electrons bound together in a singlet state (characterized by opposite spins) with a finite binding energy due to an attractive interaction.

Critical Magnetic Field: Characteristic magnetic field at which superconductivity in a type I superconductor is destroyed.

Critical Temperature: Transition temperature for the phase transition from the normal state with average zero superconducting order parameter to the superconducting state characterized by a nonzero order parameter.

Demagnetization Factor: Tensor quantity describing the difference between the external field outside a magnetized sample and the internal field. Only defined for ellipsoidal geometries, where the magnetization is homogeneous.

Energy Gap: Characteristic gap in the quasiparticle excitation spectrum of a superconductor corresponding to the binding energy of the Cooper pairs.

Flux Line: Magnetic flux penetrating a superconductor in the mixed state. Corresponds to the volume in which the superconducting order parameter is locally suppressed. In clean superconductors, flux lines arrange themselves in a regular triangular lattice (Abrikosov lattice).

High-Temperature Superconductors: New class of superconductors discovered in 1986. See SUPERCONDUCTIVITY, HIGH TEMPERATURE.

Intermediate State: Equilibrium state assumed by a type I superconductor with nonzero demagnetization factor in magnetic fields close to the critical magnetic field, characterized by the coexistence of superconducting and normal domains inside the superconductor.

Isotope Effect: Dependence of the superconducting transition temperature T_c on the atomic mass M of a constituent of a superconductor. Indication for a phonon-mediated pairing mechanism.

Josephson Effects: Appearance of a dc supercurrent across an unbiased Josephson junction (dc Josephson effect) and of an oscillating supercurrent across a junction biased to a voltage (ac Josephson effect).

Josephson Junction: Area of locally reduced order parameter separating two superconducting regions.

Low-Temperature Superconductors: Superconductors with transition temperatures T_c below ~23 K, the highest T_c achieved before the discovery of the cuprate high-temperature superconductors.

Magnetic Penetration Depth: Characteristic length over which magnetic fields decay inside superconductors.

Meissner Effect: The expulsion of magnetic field H from the interior of a superconductor (except for a surface sheet with a thickness corresponding to the magnetic penetration depth), so that the magnetic induction B remains zero inside the superconducting sample.

Meissner Phase: Equilibrium state of a superconductor characterized by complete flux expulsion.

Mixed State: Equilibrium state assumed by a type II superconductor above a characteristic field H_{c1}. Characterized by the penetration of magnetic flux into the superconductor in the form of flux lines, which, in a clean superconductor, arrange themselves in a triangular lattice (Abrikosov flux lattice).

Order Parameter: Phenomenological complex quantity for the description of the superconducting phase transition corresponding to the degree of superconducting ordering.

Persistent Current: Electrical current loop in a superconductor, which decays only with an extremely long time constant.

Pinning Center: Area of locally reduced order parameter due to defects or impurities within a type II superconductor, where it is energetically favorable for flux lines to be located, resulting in an effective force acting on the flux line.

Shapiro Steps: Constant-voltage steps in the *I-V* characteristics of a biased Josephson junction irradiated with microwaves.

Shubnikov Phase: Same as **Mixed State.**

SQUID (Superconducting Quantum Interference Device): Superconducting loop with one or more Josephson junctions exhibiting characteristic dependences of the critical current on the magnetic flux threading the loop. See SQUIDs.

Superconducting Coherence Length: Characteristic length describing the spatial range of the superconducting electron pair wave function.

Thermodynamic Critical Field: Characteristic magnetic field defined by the magnetic energy density that corresponds to the difference in free-energy densities between the superconducting and normal states in the absence of a magnetic field.

Type I Superconductor: Superconductor characterized by complete flux expulsion (see **Meissner Phase**) below a critical magnetic field.

Type II Superconductor: Superconductor characterized by complete flux expulsion (see **Meissner Phase**) below a characteristic lower critical field, the penetration of magnetic flux in the form of flux lines (see **Mixed State**) above this field, and the transition to the normal state at a second characteristic field, the upper critical field.

Weak Link: see **Josephson Junction.**

INTRODUCTION

It has been said that surfaces are the "seats of communication" between two phases. Atoms and molecules to the greatest extent sense or know about other energetic or reactive atoms or molecules that constitute a different phase only if they are at the surface. Thus processes at surfaces control the changes that occur for a large fraction of all possible physical and chemical processes. Upon formation of a surface, or more generally an interface, the surface atoms have a unique electronic structure and often geometric arrangement that is different from those atoms in the bulk phase because of the abrupt termination of the homogeneous, bulk environment. This altered structure induces new, altered chemical and physical properties for surfaces compared to the corresponding bulk phases, such as enhanced reactivity or lower melting point. Also, it is necessary to introduce separate descriptions

of the thermodynamics of the interfacial regions, such as indexing separately the surface and bulk contributions to the entropy, and to catalog new thermodynamic state variables such as the surface tension for liquids and stress tensor for solids.

It is exceedingly important to understand surfaces, and the adsorbed layers present at surfaces, since the physical changes and chemical reactions that occur there underpin practical applications in many scientific fields, important technologies, and industrial processes. Table 1 illustrates just a few of the myriad of applications where surfaces play a key role. Historically, heterogeneous catalysis, which is at the heart of the huge chemical and oil-refining industries, provided impetus to understand the structure of solid surfaces and the chemical reactions that occur there. Perhaps the greatest efforts currently involve applications in materials science and engineering, such as the processing of Si and SiO_2 for microelectronic device manufacture, development of high-temperature superconducting films, and synthesis of ultrathin metal films and quantum dots with unique electronic and magnetic properties. These driving forces along with great instrumental developments in physics and physical chemistry have led to the emergence since the mid-1960s of the field of surface science—the study of surface processes. A great deal is now known about surfaces, mostly solid surfaces, and about surface processes, but a complete description and understanding of any but the most elementary process is still not possible. The surface science field is a vibrant one as advances are made toward an overarching goal of atomic-level design and manipulation of materials.

Since gases are miscible at all proportions, possible interfaces are S/S, S/L, S/G, L/L, and L/G, where S, L, and G denote solid, liquid, and gas phases, respectively. Table 2 shows a partial listing of processes that occur at the different interfaces. Primarily as a result of the analytical capabilities currently available, the most fundamental information is known about solid surfaces and interfaces involving solids. This article emphasizes an elementary and atomistic point of view in describing some of the major types of surface processes and so focuses on solid surfaces and in particular on the gas–solid or vacuum–solid interface. For a detailed treatment of the nature and thermodynamics of liquid interfaces, surface films on liquid substrates, and the solid–liquid interface, the reader is referred to the classic text by Adamson (1990). The interested

Table 1. Surfaces play a key role in a wide variety of technological processes.

Field	Processes or materials
Biochemistry	Membranes, colloids
Catalysis	Oil refining, natural gas conversion, chemical production
Combustion	Catalytic ignition, pollution control, soot formation
Electronics	Semiconductor and solid-state device fabrication and performance
Fusion	Plasma/wall reactions
Lubrication	Friction, high-temperature service
Mining	Geochemistry, recovery
Paints and Coatings	Adhesion, corrosion inhibitors
Plastics	Production, molding
Solar Energy	Mirror technology, photochemistry
Space Exploration	Vacuum/material interfaces, space shuttle "glow"
Surfactants	Soaps, foams, emulsions

Table 2. Processes and effects at different interfaces between the solid (S), liquid (L), and gas (G) phases.

Interface		Surface processes and effects
$\frac{\text{Gas}}{\text{Solid}}$	G/S	Adsorption, catalysis, condensation and nucleation, corrosion, CVD, desorption, diffusion, energy transfer, etching, oxidation, permeation, reaction, surface states, thin-film growth
$\frac{\text{Liquid}}{\text{Solid}}$	L/S	Adsorption, capillarity, catalysis, cleaning, corrosion, electrochemical effects, etching, friction, ion electromigration, lubrication, nucleation and growth, optical properties, reaction, spreading, wetting
$\frac{\text{Solid A}}{\text{Solid B}}$	S/S	Abrasion, adhesion, corrosion, creep, delamination, diffusion, epitaxial growth, friction, grain-boundary, passivation, nucleation, reaction, segregation, solid-state device fabrication, thin-film growth, wear

reader is also referred to the recent monograph by Sutton and Balluffi (1995) for the basic ideas and principles relating to solid–solid interfaces.

1. SURFACE STRUCTURE

The cleavage of a solid forms two additional surfaces. The new surface atoms that were previously embedded in a well-defined and ordered bulk environment now suddenly lack some of their neighboring atoms and consequently some of their interactions. Thus, there exist large changes in the coordination number (number of bonding neighbors) and electrical potential at an interface or surface compared to that in the bulk phase. This dramatically affects the electronic and geometric structure of surfaces, along with the surface composition in multicomponent systems. Since the surface structure imparts the specific chemical and physical properties of the surface, we begin with a discussion of changes that are inherent to a solid surface.

1.1 Thermodynamics of Surfaces

A proper thermodynamic description of a system with a free surface must include an extensive variable A, the surface area, and an intensive variable γ, the surface tension. Additional surface contributions to the Gibbs free energy G per atom may be defined by

$$N^{\mathrm{tot}}G^{\mathrm{tot}} = N_{\mathrm{B}}G + AG^{\mathrm{S}}, \qquad (1)$$

where N_{B} is the number of atoms in the bulk and G^{S} is the Gibbs free energy per unit area. Similar expressions exist for other thermodynamic variables, e.g., enthalpy H and entropy S, where H^{S} and S^{S} indicate their respective surface contributions. Since solids do not spontaneously cleave, formation of a surface must increase the free energy. The change in total free energy due to increasing the surface area of an isotropic solid is equal to the reversible work dW^{S}, given by

$$dW^{\mathrm{S}} = \left(\frac{\partial(AG^{\mathrm{S}})}{\partial A}\right)_{T,P} dA = G^{\mathrm{S}}dA + A\left(\frac{\partial G^{\mathrm{S}}}{\partial A}\right)_{T,P} dA. \qquad (2)$$

The first term of the sum in Eq. (2) is the work spent to form a unit area of surface, and the last term is the work required to stretch the surface, which involves the surface stress. The last term of Eq. (2) vanishes for liquids because G^{S} does not depend on the area; work is only required to form additional unit surface area, and G^{S} is identified as the surface tension γ. In the case of solids, the surface tension and the surface stress are not the same. Also, for anisotropic solids we require formulation of a surface stress tensor since the extent of stretching (strain) induced by a given force depends on the direction of the force. Tables for liquid surface tensions are commonly available, and these can provide a rough guide for solids. Refractory metals have some of the highest surface tensions (≈150 kJ/mol), with lower values for oxides and other compounds, and the lowest values are for organic solids and polymers ($\gamma_{\mathrm{Teflon}} < 0.5$ kJ/mol). The presence of surface tension has several important consequences for solids: Small particles assume a spherical shape (within the constraints of their crystalline structure), and nanometer-size particles have increased vapor pressure and reactivity.

1.2 Surface Defects and Dislocations

Practical surfaces of crystalline solids exhibit simple structural imperfections (defects) on an atomic scale. Steps and kinks (at the intersection of steps) occur as the macroscopic angle of the surface with respect to a crystalline symmetry direction is produced with low–free-energy atomic planes. Isolated atoms (adatoms) and missing atoms (vacancies) on the flat terraces also exist as point defects as shown in Fig. 1(a). The reduced coordination number (number of bonding neighbors) of defect atoms induces changes in the electronic structure at these locations and imparts special reactivity. The presence and distribution of steps affects the growth rate of thin films because steps serve as preferential adsorption sites.

Line defects of the bulk structure, such as edge or screw dislocations, may extend to the surface. Figure 1(b) illustrates how a screw dislocation produces a ledge on the surface, providing altered adsorption and nucleation sites. Grain boundaries at the intersection of separate crystalline regions are

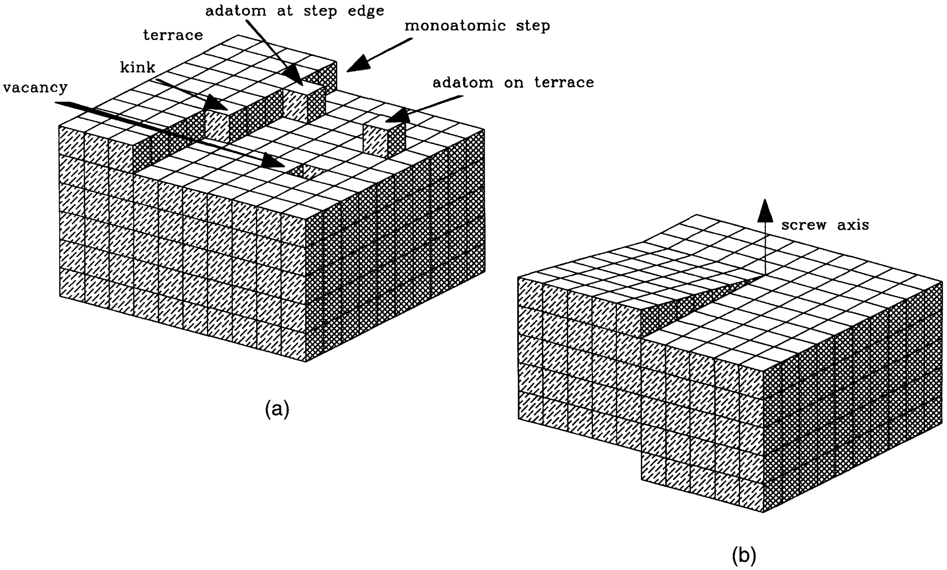

FIG. 1. Schematic representation of surface defect structures. (a) Terraces, steps, kinks, adatoms, and vacancies. (b) A screw dislocation emerges at the surface.

preferential pathways for the interlayer diffusion of atoms.

Heterogeneous defect structures are formed or induced by impurity atoms (such as C, S, and O for metals and alloys) or aggregates that affect the surface stress and the equilibrium arrangement of surface atoms. Minimization of the total energy of the actual surface structure (including defects) is the driving force for structural changes. A common defect evolution via the diffusion of adatoms, however, is often controlled kinetically, so that the surface does not necessarily correspond to its equilibrium structure.

1.3 Relaxation and Reconstruction

Surface atoms rearrange into positions away from those expected from the ideal termination of the bulk lattice in order to achieve a new, more energetically favorable configuration. The properties and reactivity of the surface are affected by this reordering. Two different phenomena are distinguished: relaxation and reconstruction.

Relaxation is the movement of surface atoms perpendicular to the surface plane. This is a common phenomenon for the closest-packed (i.e., lowest Miller index) planes of metal surfaces, such as the fcc (111) surfaces of Pt or Ni. The interlayer spacings between the first and the second layer, d_{12}, the second and the third layer, d_{23}, etc., deviate slightly from the bulk value d_B. Generally, the relaxation $(d_{12} - d_B)/d_B$ is (1–4)% of the nearest-neighbor distance for transition metals, but the more open the surface (increasing surface roughness) the larger the relative deviation can be, and these values can exceed 15%. In some cases it has been found that the values for d_{12} and d_{34} are smaller than d_B, while the value for d_{23} is increased compared to d_B. Relaxation and this oscillatory behavior of the different interlayer spacings have been measured extensively by low-energy electron diffraction (LEED). Prediction of these oscillations and comparisons to experiment provide an active test bed for theoretical treatments of the energy minimization problem at metal surfaces.

Reconstruction is a term describing large displacements of the surface atoms in three dimensions from those positions expected from the bulk lattice. This is a dominant process for solids characterized by highly directional, covalent bonding of the atoms, such as in semiconductors. The creation of a Si(100) or Si(111) surface initially leaves the Si surface atoms with an unsaturated valence. Eliminating these broken bonds, called "dangling bonds," drives the reconstruction of Si surfaces: atoms change positions to saturate these bonds, i.e., minimize the number of dangling bonds. This is achieved via a so-called 2 × 1 reconstruction to give rows of Si dimers (pairs of atoms) with a 2 × 1 surface net for Si(100) and by a very complex 7 × 7 reconstruction of the clean Si(111) surface that extends over three layers. The latter surface structure was unresolved for many years until it was determined using electron diffraction and verified by several techniques including scanning tunneling microscopy (STM). Figure 2 shows a structural model along with a STM image of this surface.

Even some metal surfaces with low–Miller-index planes, e.g., the fcc (110) surfaces of Au, Pt, and Ir, reconstruct forming "added-row" structures, and those with high–Miller-index planes reconstruct to form ordered step arrays in order to maximize the concentration of the low-free-energy, low–Miller-index planes.

Surface reconstructions occur for all compound semiconductors and for surfaces of oxides and other compounds, but much less information exists on the structures of these materials on account of the difficult problem of determining and controlling their surface composition and stoichiometry under conditions suitable for surface analysis. It is of great interest to know more about the surface structure of molecular solids, e.g., solid water (ice), energetic materials such as propellants, polymers, and model membranes, but these materials are very sensitive to damage by probing electron or ion beams

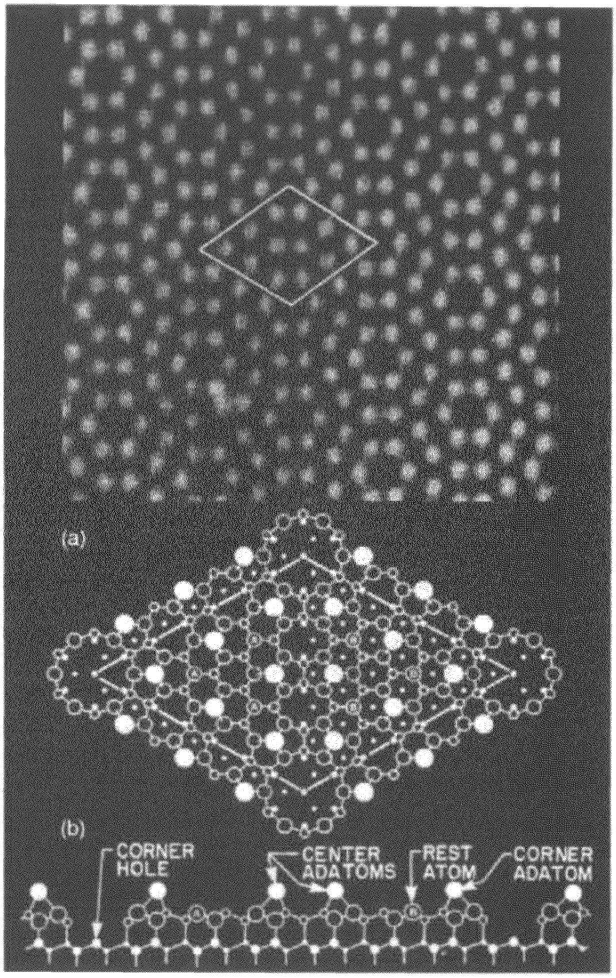

FIG. 2. The "7 × 7" reconstruction of the Si(111) single-crystal surface. Top: A STM image on which a surface unit cell (rhombus) has been overlaid (from Wiesendanger, 1994). Bottom: Schematic drawing of this surface showing large-scale atomic displacements away from those positions for a simple termination of the bulk lattice. (From Takayanagi *et al.*, 1985.)

used for analysis and are just now starting to yield to detailed investigations.

1.4 Surface Segregation

Multicomponent systems have a different surface composition compared to the bulk. This phenomenon is called surface segregation and is largely due to different surface free energies for the individual components. In the simplest approach, using ideal-solution theory for a binary system AB, the component with the lowest surface free energy will be found at the surface in a concentration given in terms of mole fractions x_i according to

$$\frac{x_A^{\text{surf}}}{x_B^{\text{surf}}} = \frac{x_A^{\text{bulk}}}{x_B^{\text{bulk}}} \exp\left(\frac{\gamma_b - \gamma_A}{RT}\right), \tag{3}$$

where R is the gas constant and T is the temperature. Since for liquid metals the surface tension is nearly proportional to the heat of sublimation ΔH_{subl} ($\gamma \approx 0.16\Delta H_{\text{subl}}$), then the metal with the lowest value of ΔH_{subl} segregates to the surface; and the bigger the difference $\gamma_B - \gamma_A$, the more different are the concentrations of the surface and bulk. For most metal alloys these effects are quite large, leading to nearly complete coverage of the surface by a component that may be present in the bulk at negligible concentrations. More accurate expressions can be developed using correction terms to account for enthalpy changes upon mixing in the regular solution model and to account for strain induced in the lattice by size differences in the components. Enhanced surface concentrations are found for the largest atoms. Segregation will occur preferentially to surface planes and positions with the highest free energies, and this has a strong effect on surface reactivity and structure, especially for small, crystalline particles typical of catalysts.

1.5 Surface Alloy Formation

Interdiffusion or intermixing (alloying) can occur to form a surface alloy film or a bulk alloy (solid solution) in the deposition of one miscible metal onto another. However, the altered environment inherent to surfaces can lead to alloying in the surface layer even when the bulk metals are completely immiscible, like in the case of Au on a Ni(110) single crystal. This phenomenon results in surface structures with novel properties.

Strong chemical bonding between the constituent atoms can lead to intermetallic compounds with a well-defined structure in the bulk and at the surface. These compounds usually have the formula A_mB_n, where m and n are integers, and the surface phase often corresponds to a structure of a crystalline plane of the bulk material. By reason of surface free energies, ordered surface phases can be formed that do not correspond to bulk crystal planes, such as in the case of an ordered, metallic γ-$FeSi_2$ surface alloy film formed by high-temperature annealing of an Fe film on a Si single-crystal substrate. Surface science methods must determine the existence and properties of such surface intermetallic phases, since they cannot be predicted by the bulk structures.

1.6 Electronic Structure at Surfaces

The 3D periodicity of the electronic potential is lost at the surface. This means that new traveling-wave solutions of the Schrödinger equation exist, and these are known as surface states—states with wave functions localized at the surface that can have energies that are not allowed within the bulk band structure. Surface states can also be created by changes in the potential due to relaxation, reconstruction, defects (e.g., emerging screw dislocations), or adsorbed impurities. These special states affect the electrical properties and the chemical reactivity of the surface by modifying the availability of filled or empty electronic states.

The localization of charge in these surface states leads to another important effect—band bending. The band structure of the bulk solid is distorted by the varying electrostatic potential on passing from the surface into deeper layers. The existence of occupied surface states can result in surface potentials on the order of millivolts or volts, and band bending can extend on the order of microns into the solid for insulators and semiconductors. Metals have negligible band bending on account of efficient screening of the surface charge by the conduction-band electrons. Surface capacitance and surface conductivity are used to probe these electronic properties (Prutton, 1983).

The work function of a solid surface controls the removal of electrons from a solid surface, affecting the contact potential between two solids, thermionic and field emission of electrons, and bonding of adsorbates. The work function ϕ is the energy difference between an electron at rest in the vacuum just outside the solid and the most loosely bound electrons inside the solid (at the Fermi energy). In addition to the attractive potential for conduction electrons in the bulk, the value of ϕ has several surface contributions: the image potential, due to electrostatic screening of charge outside of a conductor; and the surface dipole layer, arising from the overextension of electron wave functions beyond the ion cores at the surface, which leads to a charge imbalance perpendicular to the surface. The work function depends on the geometry and composition of the surface, the presence of surface roughness and defects, and the concentration and nature of adsorbed layers. Typically the value of ϕ is measured via the photoelectric effect, and work-function changes $\Delta\phi$ are sensitively monitored by capacitance methods such as the Kelvin probe.

2. ENERGETIC-PARTICLE–SURFACE INTERACTIONS

Surface processes involving energetic particles (photons, electrons, and ions) form the basis for surface analytical spectroscopies and for state-of-the-art processing methods for producing solid-state electronic devices. Depending on the energy and momentum transfer of the interaction of these particles with condensed matter, these processes may be quite varied, ranging from nondestructive probing of surface vibrations with IR radiation to atom ejection caused by impact of high-energy ions. We provide here a brief and phenomenological overview of several of these important interactions. We discuss the interactions of energetic particles with clean and *adsorbate-covered* surfaces. This is appropriate since surfaces are usually covered with monomolecular layers (monolayers) or thin films of adsorbed atoms and molecules, and these layers are important to many processes.

2.1 Photon–Surface Interactions

The interaction of photons with surfaces may be divided into photoabsorption, reflection, and scattering. Photoabsorption causes specific elementary excitations (ionization or electronic and vibrational transitions) in the substrate or adsorbed layers. Additional transitions are possible at surfaces as a result of the presence of surface states, surface plasmons (collective electron excitations), and surface phonons (collective lattice vibrations). The excitation energies and excited-state lifetimes of molecules in adsorbed layers are modified through the bonding to the surface. Photodesorption, photofragmentation, and photon-stimulated desorption (PSD) alter surface layers by breaking bonds. PSD causes desorption of atoms and molecules from surfaces due to nonthermal mechanisms under irradiation of ultraviolet (UV) or higher photon energies. The bulk photoabsorption technique of extended x-ray absorption fine structure (EXAFS) can be applied to surface atoms in SEXAFS where the photoabsorption signal is monitored with surface sensitivity by means of the secondary-electron yield or Auger electrons. In SEXAFS, as in EXAFS, oscillations appear as fine structure above the absorption edge due to interference between the emitted photoelectron wave and the waves backscattered from adjacent atoms, and subsequent Fourier analysis yields surface structural information.

The dielectric response of the surface can be derived by determining the surface contribution to the reflectivity. The simplest approach is to consider the substrate, surface, and ambient as three phases separated by sharp boundaries. The surface contribution may then be from the outermost layer(s) of the substrate or from molecular layers adsorbed on the substrate. Assuming that the thickness of the surface layer is small compared to the wavelength of the light, one can calculate the differential reflectivity $\Delta R/R$ with and without the surface layer. The value of $\Delta R/R$ is related to the imaginary part of the complex dielectric function, Im ϵ, that is associated with the surface layer. This model has been successfully applied to some electronic transitions on semiconductors and vibrational excitations in adsorbed layers. Ellipsometry (*q.v.*), one of the oldest surface-sensitive techniques, utilizes measurements of the elliptically polarized light that results from reflection of plane-polarized light from a solid surface to determine concentrations of adsorbed layers and surface film thicknesses. In recent years, using IR reflection from surfaces has become one of the most powerful probes of vibrations and identifying the species present in adsorbed layers.

The scattering of high-energy photons as applied in grazing-incidence x-ray scattering or x-ray standing-wave (XSW) analysis is an increasingly important tool in surface science. This method uses intense synchrotron radiation and very low angles of incidence (within 12° of the surface plane) to achieve total external reflection accompanied by an evanescent wave propagating along the surface to enhance the signal from the surface in x-ray diffraction studies.

Photochemical and photoprocessing technologies involve surfaces. For example, light absorption in the near-surface region of semiconductors is an elementary step in the operation of photovoltaic (solar) cells, and photocatalysts utilize light absorption by the surface region of an oxide such as TiO_2 to generate very reactive surface species that can oxidize and decompose biomaterials and chlorinated organic pollutants. Absorption of intense laser light by a solid heats surfaces and thin films to the melting point (or beyond) in 10^{-12} s. This interaction is the basis for sources used to inject nonvolatile materials (e.g., large biomolecules) into mass spectrometers, flash-annealing and quenching materials processing, and laser-induced thermal desorption (LITD) that has been used to study surface diffusion and reactions.

2.1.1 Photoelectron Emission (Photoemission) Photoelectron emission spectroscopy is based on the photoelectric effect. Light incident on solid surfaces produces free electrons from the surfaces when the energy of the incident light exceeds the work function ϕ of the sample. Energy conservation requires that the kinetic energy E_K of the emitted photoelectron is given by the difference between the photon energy $\hbar\omega$ and the binding energy E_B of the electron in the solid, according to the equation $E_K = \hbar\omega - \phi - E_B$. Ultraviolet photoelectron spectroscopy (UPS) uses 5–40-eV photons to probe sensitively the valence electronic structure of both the substrate surface and adsorbed layers at the surface. Angle-resolved photoemission has been a powerful tool for determining the energy and dispersion of the electronic band structure of crystalline solids and for studying surface states. A dipole selection rule governs photoemission, and a simple form of the matrix elements can be expressed as $\langle f|\mathbf{p}|i\rangle \cdot \mathbf{A}$, where i and f denote the initial and final state, respectively, $\mathbf{p}$ is the momentum operator, and $\mathbf{A}$ is the vector potential of the electromagnetic field. By constraining the outgoing photoelectron final state (with the detector direction) and controlling the polarization vector of the incident light, one can derive straightforwardly selection rules for the initial states that are dipole-allowed and thus the orientation of adsorbed molecules can be determined. The majority- and minority-spin states in ferromagnetic systems can be distinguished if one uses spin-polarized sources and detectors. In inverse photoemission, electrons incident on the surface transiently occupy empty electronic states and provide a mapping of the unoccupied density of states.

Binding energies of electrons in atomic core levels are characteristic of the probed atom. X-ray photoelectron spectroscopy (XPS), also known as electron spectroscopy for chemical analysis (ESCA), is used for quantitative elemental analysis of surfaces. Small changes in these core-level binding energies due to changes in the number of valence electrons (oxidation state) make XPS a rather unique probe of the chemical state of atoms at surfaces, e.g., distinguishing Fe^0 in metallic Fe from the oxidized Fe^{+3} in Fe_2O_3. A different binding energy occurs for electrons in core levels of atoms at the surface compared to the bulk—the surface core level shift. In x-ray photoelectron diffraction (XPD), the photoemission intensity at a particular energy is measured as a function of the incident photon energy (using synchrotron radiation) and/or the emission angle. Modulation of this intensity occurs by interference of the directly emitted photoelectron wave with parts that are backscattered from neighboring atoms. This gives local information on distances to adjacent atoms in the substrate or adsorbate, orientation of molecules on surfaces, and overlayer growth modes.

2.1.2 Electromagnetic Fields at Surfaces

There are a range of phenomena particularly associated with the electromagnetic fields at surfaces. For example, giant enhancements (by factors of 10^6) can occur in the Raman-scattering cross section on surfaces, especially for roughened silver surfaces. Surface-enhanced Raman scattering (SERS) thus became a viable vibrational spectroscopy for surfaces even though the Raman effect is a weak one. The large surface enhancement is primarily caused by the strong local electric-field enhancements from local plasmons associated with small structural features on the surface but also includes some additional local property associated with changes in the electronic states of the system due to chemical bonding.

Second-order nonlinear optical processes are allowed necessarily at surfaces or interfaces, but they are forbidden in media containing inversion symmetry. This specificity makes two second-order nonlinear optical spectroscopies, second harmonic generation (SHG) and sum-frequency generation (SFG), unusually surface sensitive. In SHG one measures a signal emerging from the sample at twice the frequency of the incident light due to a nonlinear optical response of the surface. In SFG one obtains a signal at the sum of the two incident light frequencies (typically visible and infrared) in order to measure vibrational spectra. Both methods allow for the determination of the second-order susceptibility $\chi^{(2)}_{\mathrm{surf}}$, from which one can obtain spectroscopic information and molecular orientation for adsorbed molecules. The high spatial, temporal, and spectral resolutions associated with lasers used in these techniques have led to a number of unique applications for probing surfaces.

2.2 Electron–Surface Interactions

The interactions of electrons with matter are usually characterized by elastic or inelastic scattering. Scattering events may induce electronic excitations that decay via the emission of light or electrons and related secondary processes. The inelastic mean free path of electrons with kinetic energies in the range between 1 eV and several keV traveling through condensed matter is typically smaller than 10 nm (100 Å). Electron spectroscopies based on the detection of electrons at those energies are surface-sensitive techniques. Inelastic-scattering events in solids include collective excitations of the electron plasma (5–20 eV), electronic (single-electron-like intraband and interband) excitations (5–20 eV), and core-level ionization (20 eV–10 keV). Incident electrons below 10 eV efficiently excite lattice vibrations (phonons) and vibrational modes of molecules at surfaces, and this causes inelastic losses that are below 1 eV.

Auger-electron spectroscopy (*q.v.*) (AES) is the most widely used quantitative probe of surface composition. In AES, an incident electron beam of 1–5 keV causes core-level ionization, and the ionized atoms relax efficiently via a two-electron nonradiative transition (the Auger process) in which another electron (the Auger electron) is emitted with an energy characteristic of the ionized atom. This technique is carried out using a finely focused, rastered incident electron beam in scanning Auger-electron microscopy (SAM) in order to obtain elemental composition maps of the surface with <500-Å resolution.

Much of the early information on surface structure and morphology and surface diffusion came from field-emission microscopy (FEM) (see FIELD EMISSION AND FIELD IONIZATION). Field-emitted electrons from a metallic tip are accelerated toward a fluorescent screen to produce a highly magnified image of the tip. The related technique of field-ion microscopy (FIM) typically uses He as an imaging gas, which is ionized by the high electrical field gradient at the sample tip, obtaining higher resolution than FEM. Electron microscopies use a finely focused beam of high-energy electrons rastered across the sample to obtain a highly magnified image of the probed area. Scanning electron microscopy (SEM) and scanning transmission electron microscopy (STEM) reveal details about surface morphology for a wide range of materials, with a resolution down to about 50 Å. Transmission electron microscopy (TEM) has atomic resolution and requires thin films as substrates, i.e., it is not inherently surface sensitive. It can be used to determine surface structure when a cross section of the film is analyzed. Electron tunneling between the sample surface and a conducting tip scanned across the surface by piezoelectric ceramic tubes is the basis for the scanning tunneling microscope (STM), a revolutionary probe of surface structure and morphology.

Electrons are useful in surface modification processes, since electron bombardment at energies exceeding a few electronvolts breaks chemical bonds at the surface. Electron-induced dissociation (EID) refers to the production of new surface species in adsorbed layers by dissociation of surface and adsorbate bonds. Following ionization of an atom or molecule, relaxation (sometimes via Auger decay) causes desorption of surface atoms or adsorbed species in a process called electron-stimulated desorption (ESD) analogous to PSD. In ESD and PSD, molecules are excited to a strongly repulsive part of a dissociative electronic state that leads to ion ejection predominantly along the ground-state bond axis. This forms the basis for the ESD ion angular distribution (ESDIAD) technique, which provides patterns like those in Fig. 3.

2.2.1 Diffraction Diffraction occurs as a special case of coherent elastic scattering of electrons by atoms in a crystalline solid and requires that the de Broglie wavelength of the electron ($\lambda = h/p$) is less than or equal to the lattice constant d. For metals, a typical d value is 3 Å, and so incident electrons with kinetic energies in the 10–200-eV range (λ = 1–4 Å) undergo diffraction. This forms the basis for an analytical technique called LEED. The diffraction (spot) pattern reveals information about the size and orientation of the unit cell of surface structures with long-range order. More detailed analysis of the two-dimensional (2D) structure of the surface is possible when the width of the diffraction spots is measured (spot profile analysis, SPA-LEED). The measurement of the spot intensity I as a function of the incident electron energy (proportional to the gun acceleration voltage V) is called IV-LEED, and dynamical scattering simulations of these curves can provide bond distances at surfaces to within 0.1 Å for small and simple unit cells. In reflection high-energy electron diffraction (RHEED), the electron beam hits the surface at grazing incidence, and the diffraction spots form a semicircle-like pattern around the specular beam spot. RHEED is performed at incident energies of 20 keV and can be used for *in situ* monitoring and investigation of film deposition and growth under vacuum conditions.

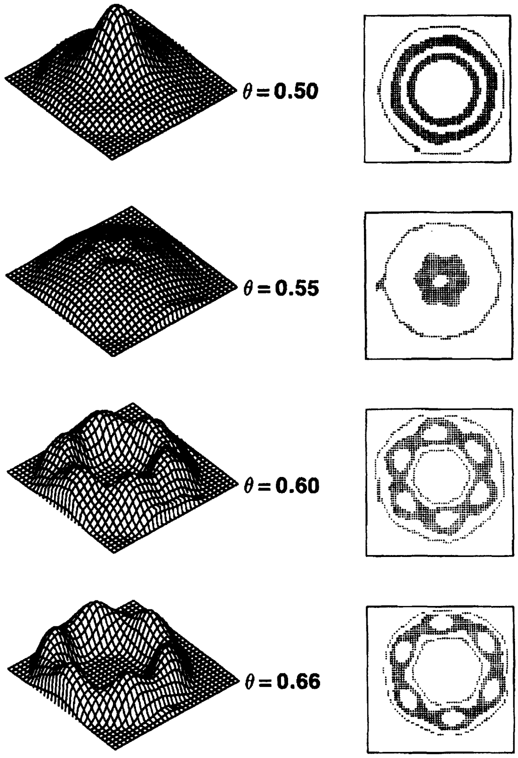

FIG. 3. ESDIAD patterns of CO^+ ions indicating particular tilt directions of the molecular CO axis with respect to the surface due to surface crowding of chemisorbed CO species (from Kiskinova *et al.*, 1988).

2.2.2 Electron Emission Historically, much of surface physics was concerned with electron emission, and electron sources are essential to a wide array of devices, such as vacuum-tube amplifiers, and all electron-beam applications, e.g., electron microscopy. Electrons emitted from a solid have to overcome the work function, which is typically about 5 eV, and so high temperatures (and thus W filaments) are required for thermionic emission of electrons. The coating of these "hot cathodes" with thorium oxide, or the use of LaB_6, reduces the work function and allows operation at lower temperatures. This reduces problems with outgassing, a desorption of adsorbed gases from thermal heating of the surrounding parts. Field emission occurs from very sharp metallic tips via electron tunneling through the narrow potential barrier at the surface caused by the application of a high negative voltage to the tip. The combination of a small tip radius and high potential creates a large electrical field gradient allowing electron emission at very low temperatures ($T \leq 300$ K). These sources are characterized by narrow electron energy distributions and small source sizes. The surface of a negative–electron-affinity (NEA) source emits electrons under the influence of only modest electric fields at low temperatures in a "cold cathode" source. This is achieved by the combination of a low–work-function material, like a Cs-covered Si surface, with a semiconductor device, where the energy level of electrons at the heterojunction (Si-semiconductor interface) lies above the Cs-reduced vacuum energy level of Si. These NEA sources are extremely interesting for a number of technologies like microwave tube applications, high-definition monitors, and flat-panel displays.

2.3 Ion–Surface Interactions

Ions incident on a surface at appreciable kinetic energies (>5 eV) impart significant momentum to the collision partner at the surface, and this energy available from ion scattering causes surface changes. In addition, neutralization via charge transfer upon collision with a surface releases energy into the incident species equal to the ionization potential of the corresponding atom or molecule. Since ions can easily be accelerated, deflected, or focused with electrostatic fields and lenses, a number of surface analytical spectroscopies have been developed using ions, most notably ion-scattering spectroscopy (ISS), Rutherford backscattering spectroscopy (RBS), and secondary-ion mass spectrometry (SIMS). The chemically reactive nature of ions has resulted in a variety of surface-processing technologies involving ions generated in plasmas near the surface or in focused beams.

2.3.1 Scattering The interaction of ions with surfaces depends primarily on the ion kinetic energy. The higher the incident ion kinetic energy, the smaller the distance of closest approach $d_{\min}$ between an incoming ion and a scattering atom. For thermal energies $d_{\min}$ is of the order of interatomic distances, and scattering happens at a potential slightly modulated by the geometry of the surface atoms. For relatively low-energy ions (0.1–1 keV) $d_{\min}$ is smaller than interatomic distances, and ions slightly penetrate into the surface but are predominantly scattered from the topmost surface layer. Severe neutralization of ions in conductors insures that scattered ions have trajectories that only probe atoms exposed at the surface. Ion interactions with surface atoms may be described in terms of a collision process between two isolated atoms of masses m_1 and m_2, under the assumption that the energy transfer is much bigger than the binding energy of the atom within the solid (a few electron volts). Simultaneous conservation of momentum and energy leads to the basic scattering equation that gives the final energy of the scattered ion (relative to the initial energy of the incoming ion) as a function of the mass ratio $A = m_2/m_1$ of target mass m_2 and projectile mass m_1 and the total scattering angle θ:

$$\frac{E_f}{E_i} = \frac{1}{(1 + A)^2}(\cos\theta \pm \sqrt{A^2 - \sin^2\theta})^2 \qquad (4)$$

This relation forms the basis for a surface analytical technique called ISS, also known as low-energy ion scattering (LEIS), that is used to obtain information on the elemental composition and the geometrical arrangement of atoms at a surface. In the simplest application the energy distribution of scattered ions is recorded using a monoenergetic incoming ion beam (0.2–5 keV) and a fixed scattering geometry. Different peaks in the final ion energy distribution belong to scatterers with different masses.

It is also possible to determine the relative geometrical position of surface atoms by utilizing the angular dependence of the scattered-ion intensity. The main phenomena that control the intensity dependence are shadowing and blocking. A shadow cone results in a region behind a scattering target atom where no ions may be found for the allowed ion trajectories. Shadowing (of other scattering atoms) by atoms along the incident ion trajectories and blocking (of the detector) by atoms along the exiting ion trajectories cause large angular variations in the scattered-ion intensities for a given geometrical arrangement of the near-surface atoms when alkali ions (which have low neutralization cross sections) are used.

The analytical technique high-energy ion scattering (HEIS), called Rutherford backscattering spectroscopy (RBS) when using α particles (He^{++} ions) typically at 1 MeV, provides unique structural information about buried interfaces and concentration/depth profiles, yet can still reveal near-surface–sensitive information. The stopping power of matter for α particles and other high-energy ions is well known, and this leads to an absolute determination of concentration in the solid. Since the average kinetic energy of the He^{++} ion that is dissipated (by long-range interactions) is proportional to the distance traveled within the solid, observation of the He^{++} ion energy loss gives a very powerful tool for high-sensitivity, nondestructive depth analysis. If the incoming beam is aligned with a high-symmetry direction of a single-crystal sample, which is often the case for many practical Si-based devices, then the scattering at the surface atoms will give rise to a so-called surface peak with a well-defined energy loss. All other ions will enter deep into the crystal—a process called channeling—and have only a low probability of being reflected into the detector. The reflected-ion intensity, however, will not be zero since scattering still occurs at imperfections or dislocations, or on account of thermal motion of the atom cores about their equilibrium positions. The geometric structure of the solid can be determined since for an arbitrary ion-beam direction all layers will contribute to the reflected ion intensity, which will be much higher than for the channeling directions.

2.3.2 Sputtering and Implantation

Ion–surface collision at ion kinetic energies above a few electronvolts can cause sufficient momentum transfer to eject surface atoms. This removal of atoms is called sputtering; it abrades the surface like an atomic-scale sandblaster. Theoretical simulations that apply energy and momentum conservation provide information on the fundamental processes that occur upon collision of an ion and a target atom, ranging from scattering and defect formation to sputtering. A sample (calculated) ion trajectory is shown in Fig. 4.

Sputtering (*q.v.*) is a common method for the cleaning of surfaces in ultrahigh vacuum (UHV), where the pressure is below 10^{-7} Torr. A beam of typically 2-keV Ar^+ ions with a current density of 10 $\mu A/cm^2$ on a sample would typically remove material from the surface at rates of 20–1000 Å/min depending on the sputtering yield, which is determined by the "hardness" of the material. When more aggressive conditions are used, i.e., very high (milliampere) ion currents, this process is called ion milling and can cause macroscopic changes in the sample morphology. Sputtering is also utilized in depth-profiling analysis of heterogeneous systems, where the surface composition is monitored at the base of an etch pit formed after gradual removal of surface layers. Secondary-ion mass spectrometry (SIMS) is based upon sputtering of the sample. In SIMS, the distribution of positive and negative secondary ions (primary ions are those of the incident beam) ejected from the surface by ion-beam bombardment is recorded.

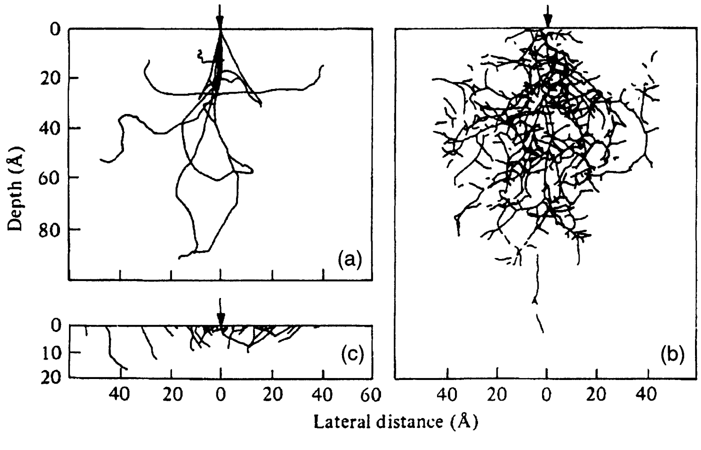

FIG. 4. Monte Carlo simulation of 4-keV Ar^+ ions incident on a target of randomly distributed Cu atoms. (a) 10 incident Ar^+ ion trajectories, (b) resulting Cu recoil distribution, and (c) the Cu sputtering events resulting from 50 incident ions. (From Ishitani and Schimizu, 1974.)

The elemental sensitivity and dynamic range of SIMS are several orders of magnitude higher than for AES and XPS, but huge variations in the neutralization efficiency of the secondary ions means that SIMS is not a quantitative probe in general.

Ion implantation can be carried out at incident ion energies of several MeV to provide a known distribution of ions (which become dopant atoms) at a specific depth within a solid substrate. At very high incident ion energies (100 keV–4 MeV) $d_{\min}$ gets so small that ions can enter deep (several microns) into a solid; the shadow cone becomes very narrow, and neutralization processes are dramatically reduced. This is a crucial commercial manufacturing process since doping of semiconductors is required for the production of microelectronic devices. For example, boron (B) is introduced into Si to produce p-doped material. SIMS using a calibration provided by the known depth profile of high-energy ion implantation, e.g., B in Si, can be quantitative and finds widespread use in quality control in semiconductor fabrication lines.

3. GAS–SURFACE INTERACTIONS

While incoming charged particles (electrons and ions) interact with a surface via a long-range attractive Coulomb potential, gases (neutral atoms and molecules) exhibit much shorter-range interactions with the surface. Four elementary processes in gas–surface interactions are adsorption, diffusion, reaction, and desorption. All surface reactions begin with collision of the gas with the surface or adsorbed layers. Gas localized at the surface is trapped or adsorbed, but still may be mobile in two dimensions and diffuse across the surface. Reactions can occur within a colliding or adsorbed molecule (e.g., isomerization or dissociation) or between coadsorbed species. Desorption is the opposite process to adsorption and results in the liberation of species from the surface into the gas phase. A schematic of these gas–surface interactions is shown in Fig. 5. Analogous processes exist for the L/G interface, and also for the S/L and L/L interfaces, where adsorptive molecules are furnished by the liquid phase(s), but these interfaces have not been studied in as much detail.

3.1 Surface Collisions

Gases impinging on a surface may be either adsorbed or reflected from the surface (not necessarily into a specular direction). The incoming flux Z (number of particles per unit time per unit area) may be rewritten as a function of the partial pressure p of the molecule in the gas phase as $Z = p(2\pi mkT)^{-1/2}$, where m is the mass and k is the Boltzmann constant, and provides an absolute upper limit to the adsorption rate. The following mainly considers collisions at thermal velocities. However, incoming gases with hyperthermal energies (0.5–5 eV) are also of interest. These interactions lead to collision-induced dissociation (CID), where momentum transfer high up on the repulsive potential, the "hard wall," dissociates the colliding molecule, but this dissociation occurs often as the molecule is leaving (has left) the surface region and all of the fragments appear in the gas phase.

3.1.1 Energy Exchange The adsorption of a gas requires minimally the loss of incident translational energy perpendicular to the surface, and this requires energy exchange with the surface. Even for gases not adsorbed, the scattered gas will generally leave the surface with a somewhat different energy and momentum as a result of the interaction. If T_i and T_f denote the temperatures in the gas phase before and after the collision, respectively, and T_s is the temperature of the surface, then the accommodation coefficient, α_T, is defined by

$$\alpha_T = \frac{T_i - T_f}{T_i - T_s}. \tag{5}$$

If there is little or no interaction between the gas and the surface, the temperature in the gas phase will not change much and α_T will be near zero. If, on the other hand, the gas resides on the surface for a time that is large compared to molecular vibration times (i.e., the gas–surface interaction energy is large), the molecule will leave the surface with $T_f = T_s$, and α_T becomes 1. Analogous expressions may be defined separately for the energy accommodation coefficient in each of the individual degrees of freedom of the gas, and quantum-state–specific information about surface-mediated energy transfer and relaxa-

3.1.2 Atomic- and Molecular-Beam Scattering Atoms with thermal energies (<0.1 eV) do not penetrate into the surface but are deflected at some distance above the surface. This atom scattering can be used as a surface structure probe. An atom beam, mostly using thermal-energy He gas, can be made monoenergetic with the aid of a nozzle beam, a skimmer, and a rotating chopper disk, and its energy can be measured with time-of-flight (TOF) techniques. This experimental setup allows measurements of the diffraction pattern from ordered hydrogen adatoms, which are usually hard to detect by electron diffraction, and a determination of the adsorbed layer structure. One can also measure the amount of the specularly reflected beam intensity compared to the diffuse scattering intensity as a function of changing surface conditions. For example, a good-quality, closed-packed fcc (111) surface shows almost no diffuse scattering, so that the intensity of the scattered atoms appears all in the specular beam. However, a surface defect like a vacancy or an adatom leads to a decrease of the specularly reflected beam intensity I_{SR}. Since I_{SR} depends nonlinearly on the number of defect structures, atom scattering is a very powerful tool for the investigation of the distribution of defect structures, growth and diffusion mechanisms, and 2D phase transitions of adsorbates.

The dynamics of gas–solid interactions can be probed by using a similar experimental setup to that for atom scattering in molecular-beam scattering (MBS) studies. In this case, a beam of molecules with well-defined parameters like kinetic energy, vibrational or rotational excitation, and in some cases even molecular orientation and alignment is directed toward a surface. Moreover, the angular and energy distribution of the reflected beam can be monitored via mass spectroscopy and other laser-based spectroscopic probes, such as laser-induced fluorescence (LIF), to determine the population of specific quantum states of the scattered product to elucidate specific energy-transfer processes occurring at the surface. This yields detailed information on elementary interactions such as energy accommodation, adsorption mechanisms, differential reaction cross sections, and the potential energy surface describing the gas–surface interaction. Activation energies for adsorption and reaction can be probed by varying the translational energy (and that of other internal degrees of freedom such as vibrational energy) of the incident molecules and the surface temperature.

3.2 Adsorption

The thermodynamics of adsorption is often evaluated phenomenologically in terms of an adsorption function $n = n(p,T)$, where n is the number of adsorbed species (per unit area) at a given temperature T and partial pressure p of the species in the gas phase. Whenever the system reacts reversibly upon changes in p or T, i.e., whenever n is a function uniquely defined by p and T, the adsorption system can be described by equilibrium thermodynamics. In analogy to gas-phase systems $n = n_T(p)$, $n = n_p(T)$, and $p = p_n(T)$ are then called adsorption isotherms, isobars, and isosteres, respectively. The shape of the isotherm was used historically to supply evidence about the interactions in the system. A plot of the isotherm is also a convenient form for the adsorption data to compare with theoretical predictions based on the assumptions in various microscopic models.

An expression for the simplest isotherm can be derived by assuming that the surface is homogeneous and the adsorbed species show no interaction with each other so that the adsorption energy is a constant. At equilibrium, the adsorption rate ($r_a = k_a p$), which is proportional to the partial pressure p in the gas phase, is equal to the desorption rate ($r_d = k_d\theta$), which is proportional to the concentration (coverage) θ of species on the surface, and this may be written in the form $\theta = kp$, with the constant $k = k_a/k_d$ being characteristic for the particular adsorption system. The resulting isotherm is simply a straight line in a plot of coverage versus partial pressure. This so-called Henry's-law isotherm has been found experimentally for only a few adsorption (physisorption) systems at very low coverages, and such behavior is not expected to hold for many real adsorption systems on the basis of the assumptions used in the derivation.

Consider now the surface to have a total number of adsorption sites n_0, of which n are occupied and hence $n_0 - n$ are empty. The adsorption rate r_a should then be proportional to the partial pressure p of the adsorptive in the gas phase and the number of empty adsorption sites, and the desorption rate r_d will be proportional to the number of adsorbed species, θ. At equilibrium the adsorption and the desorption rates are equal, and this results in the Langmuir adsorption isotherm

$$\theta = \frac{kp}{1 + kp} \quad \text{or} \quad \frac{1}{n} = \frac{1}{kn_0 p} + \frac{1}{n_0}. \qquad (6)$$

This expression implies that for low p the adsorbed amount θ is proportional to p (this gives the Henry isotherm) and that at high pressures n reaches the saturation value n_0 (i.e., $\theta = 1$). The right-hand form shows that n_0 and k may be determined from the slope and intercept of a plot of $1/n$ versus $1/p$. An independent derivation from statistical thermodynamics results in a functionally identical relation. Both derivations may formally be made equivalent if the internal partition functions of the molecule in the gas phase and on the surface are assumed to be the same. In general this condition is not met because the adsorption process will at least affect the rotational degrees of freedom on account of the interaction with the surface, and the Langmuir adsorption isotherm has to be modified for a more accurate description.

One can easily derive a Langmuir isotherm also for the case of dissociative adsorption. Considering the adsorption of

A_2(gas) at an adsorption site on the surface, denoted as *, to form 2A(ads) as in

$$A_2(\mathrm{gas}) + 2^* \leftrightarrow 2\mathrm{A(ads)}, \tag{7}$$

the Langmuir isotherm for dissociative adsorption then becomes

$$\theta = \frac{k\sqrt{p}}{1 + k\sqrt{p}}. \tag{8}$$

Brunauer *et al.* (1938) (BET) have extended the approach by Langmuir to the important case of multilayer adsorption. They assumed a Langmuir-type behavior for each layer, with the heat of adsorption being Q for the first layer and Q_v (heat of condensation of the liquid layer) for the following layers, with a further assumption that evaporation and condensation can only occur from or on exposed surfaces. With just one parameter it is possible to determine surface areas from adsorption data and knowledge of the adsorbate size (cross-sectional area). Although this BET isotherm does not describe the experimental data over the whole pressure range, it has found widespread application for commercial rapid determination of the surface area of solids. More refined model isotherms have been derived, but they also introduce one or more additional parameters.

Surface lifetimes are key factors in a wide variety of surface processes. Under the limiting conditions of Henry's isotherm, n may be rewritten as $n = Z\tau$ with τ denoting the lifetime of the molecule on the surface. In the presence of attractive forces the lifetime is given by $\tau = \tau_0 \exp(Q/kT)$, where $\tau_0 = h/kT$ is a characteristic vibrational time (e.g., $\tau_0 \approx 10^{-13}$ s for $T \approx 500$ K), Q is the enthalpy of adsorption, and T is the substrate temperature. Thus, τ is very short for small values of Q and high T, and increases strongly with increasing Q and decreasing T.

The number of adsorbed species n can be related more generally to the incoming gas flux Z with the introduction of a sticking coefficient S defined as $S = r_a/Z$, where the adsorption rate $r_a = dn/dt$. Recalling that Z may be written as a function of the partial pressure p of the molecule in the gas phase, S is determined from the experimental measurement of the adsorption rate as a function of the partial pressure. Expressions for S are generally of the form $S(\theta,T) = S_0(T)S(\theta)$, with S_0 denoting the initial sticking coefficient on the clean surface and $S(\theta)$ accounting for the influence of coadsorbed (see below) molecules on the adsorption (uptake) rate. S_0 is a temperature- and structure-sensitive characteristic of the molecule–surface bonding, with values ranging from 10^{-8} to 1. Simple expressions for $S(\theta)$ are $1 - \theta$ and $(1 - \theta)^2$ for nondissociative and dissociative Langmuir adsorption, respectively. The presence of weakly bound "precursor" adsorption states allows for diffusion prior to desorption and causes values of S on adsorbate-covered or chemically modified surfaces to be higher than that predicted by Langmuirian kinetics. At low coverages, S can even be a constant, i.e., independent of the adsorbate coverage.

Coadsorption, the presence of two or more species on a surface, is a common requirement for surface reactions. A second species in the adlayer also alters the local environment of adjacent adsorption sites and modifies the reactivity of the surface by simply "blocking" (occupying) potentially reactive sites and/or by directly or indirectly altering the electronic structure of the surface. For example, submonolayer coverages of alkali metal atoms on transition metals redistribute electron density at the surface and cause a large decrease of the work function. This affects the probability and extent of electron-transfer reactions at the surface and the nature and energetics of adsorption of coadsorbed molecules. The influence of such "modifiers" on reactions at the surface is the origin of promotion (enhancement) and poisoning (reduction) in heterogeneous catalysis and affects the designed modification of surface properties.

3.2.1 Physisorption and Chemisorption

The nature of the gas–surface adsorption interaction distinguishes two processes: physisorption and chemisorption. Physisorption is adsorption on a surface caused by long-range electrostatic, van der Waals forces, i.e., weak, nondirectional interactions between closed-shell atoms and molecules. This includes dipole ↔ dipole, dipole ↔ induced dipole, and dispersion forces (induced dipole ↔ induced dipole) with an interaction potential U proportional to $1/r^6$. Interaction energies are typically lower than 30–40 kJ/mol, being only a little larger than the heat of vaporization of the bulk (condensed) phase of the adsorptive. Physisorption forces operate for any system, including on top of a chemisorbed layer (giving rise to multilayer adsorption). There is minimal evidence for perturbations of the electronic states of adsorbate and adsorbent, the adsorption is not an activated process, equilibration is rapid and often limited by transport processes, and the coverage responds to changes in the partial pressure p and the temperature T.

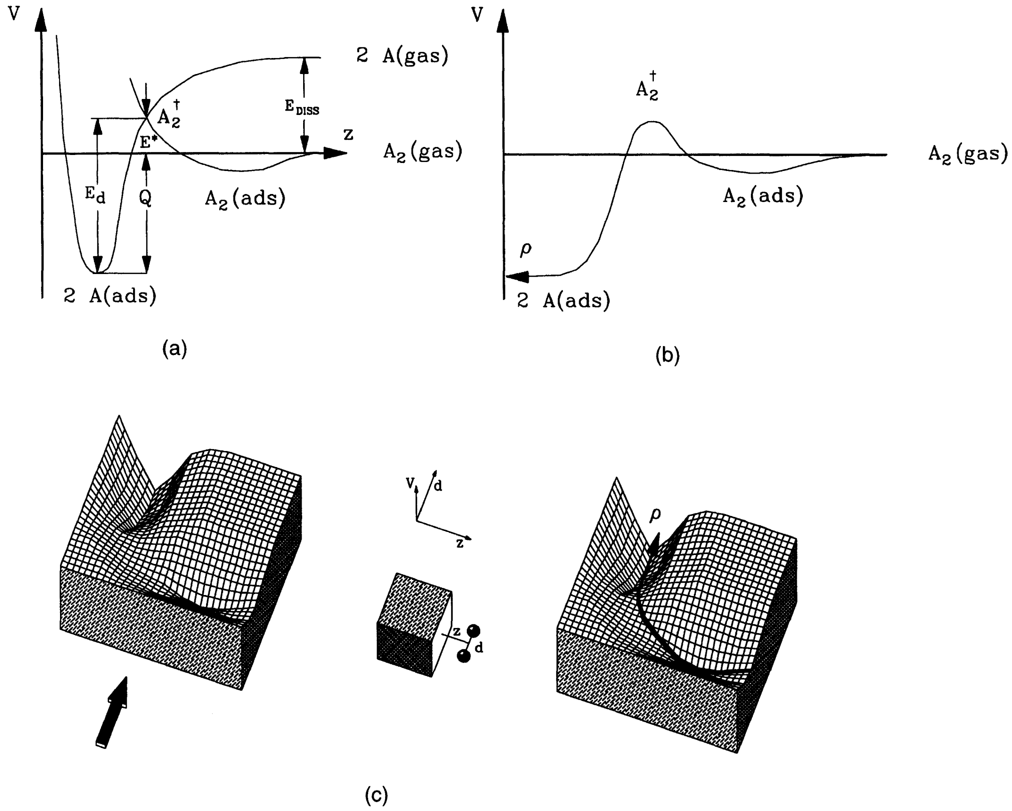
On the other hand, chemisorption involves chemical bonding interactions (covalent, ionic, or dative) usually greater than 40 kJ/mol, i.e., it is chemically specific and therefore depends strongly on the surface and adsorbate identity and structure. The adsorbate occupies specific locations (adsorption sites) on the surface. This does not necessarily imply that the adsorbate is frozen at these sites, because mobile adsorbates can diffuse across the surface, but as a time average the adspecies will be preferentially located in specific adsorption sites and not be randomly distributed. The chemical nature of the adsorptive gas may be altered by surface dissociation or reaction (and this may not be reversible), and changes in the electronic states of the substrate surface are often detectable. The elementary adsorption step is often activated (for dissociative adsorption), and a true equilibrium is only slowly achieved if the activation energy is large. The saturation coverage (maximum surface concentration in the monolayer) is on the order of $\theta = 10^{14}$ molecules/cm^2. This is obtained even at very low pressures and is insensitive to small changes in p and T.

3.2.2 Potential-Energy Diagrams The interaction of a molecule and a surface is usually discussed in terms of a one-dimensional (1D) potential function $U(r)$, which is similar to a pairwise potential for two molecules. The Lennard–Jones potential

$$U(r) = 4\epsilon\left[\left(\frac{\sigma}{r}\right)^{12} - \left(\frac{\sigma}{r}\right)^{6}\right] \tag{9}$$

can be expressed with only two parameters, ϵ and σ, and is a reasonably realistic potential for nonpolar, spherical molecules. It can be used to describe adsorption interactions, with r set now equal to the height of the adsorbate above the surface. For a complete description of adsorption, physisorption and chemisorption interactions must be considered, and a discussion of dissociative chemisorption must consider the interactions of both the molecular and dissociated species. Two potential curves describe the two processes, each with a different interaction energy (well depth) and height of the adsorbate above the surface (equilibrium bond distance). Consider the dissociative adsorption $A_2(\text{gas}) \rightarrow 2\ A(\text{ads})$ as depicted in Fig. 6. Incoming molecules usually follow an adiabatic pathway along the lowest-energy curve, passing through the molecularly chemisorbed well and on into the dissociatively chemisorbed well if energetically possible. Commonly, the plot of the potential energy versus the distance z perpendicular to the surface will exhibit a local potential maximum between the minima of these two chemisorption wells. The position of this maximum with respect to the reference potential, where the free molecule is at some large separation from the surface, determines the activation energy E^* for dissociative chemisorption. If E^* is negligible, i.e., the temperature coefficient of the adsorption rate is very small, the chemisorption is said to be unactivated and adsorption rates can be high even at low temperatures. Activated adsorption is required if there is a significant E^*, and adsorption rates are low at modest temperatures and strongly temperature dependent. This energetic barrier results from a correlation of the dissociatively chemisorbed species to the free molecular fragments (or to an excited state of the free molecule in cases of activated nondissociative chemisorption where a barrier emerges between the physisorbed and chemisorbed wells).

These diagrams are also useful to discuss the system thermochemistry, showing clearly endothermic or exothermic adsorption enthalpies, Q, the activation energies for the respective desorption processes, and derived surface-adsorbate bond strengths. Consider some experimental results on hydrogen adsorption on transition metal surfaces (Gasser, 1985). The dissociative chemisorption of H_2 on Pt surfaces is not activated, i.e., $E^* \approx 0$, and so the measured activation energy for desorption corresponds to the heat of ad-



(a)

(b)

(c)

FIG. 6. Schematic potential energy diagrams for a diatomic molecule A_2 interacting with a surface to form an adsorbed A_2 molecule, A_2(ads), and dissociating to form two adatoms, 2A(ads), with its bond axis (bond length *d*) parallel to the surface at distance *z*. (a) 1D Lennard–Jones diabatic curves *V*(*z*), where *z* is the distance of the adsorbate perpendicular to the surface, showing the correlation between gaseous and adsorbed species, (b) variation of the potential energy *V*(*ρ*) along an adiabatic path for the reaction coordinate *ρ*, and (c) 2D potential-energy surface *V*(*z*,*d*), where *d* is the A_2 intramolecular bond length.

sorption. For the dissociative chemisorption of H_2 on copper, $E^* > 0$ and the energy required for the desorption process is given by $E_d = Q + E^*$. Endothermic ($Q > 0$) dissociative chemisorption of H_2 on gold results in a desorption energy given by $E_d = E^* - Q$. In this latter case it is not possible to form H(ads) from H_2(gas), but one still can still form H(ads) from gas-phase H radicals or from sufficiently activated (excited) hydrogen molecules H_2^*(gas).

These 1D models may be used to evaluate some of the basic interactions, but a more accurate description of surface processes and dynamics of surface interactions certainly has to include more than one coordinate. A plot of the potential energy versus both the distance *z* of the molecule from the surface and the interatomic separation *d* within the molecule gives a 2D potential energy surface. The local minimum at large *z* corresponds to the molecular precursor state, the local maximum to an activated intermediate complex and the valley at low *z* to the dissociated state. Analogous plots are used to describe the progress of chemical reactions (see Sec. 4) as introduced by Eyring and Polanyi (Eyring *et al.*, 1974–1975). The dynamics of surface reactions are best discussed in terms of these 2D potential-energy surfaces. Trajectories on the surface are associated with a continuous transformation of energy between the different degrees of freedom of the adsorbed complex, and one can evaluate the influence of translational, rotational, and vibrational excitations in the incident gaseous molecules on reaction probabilities and paths.

3.3 Diffusion

The diffusion coefficient $D(B)$ for moving particles B on a surface A is defined by Fick's first law:

$$J(B) = -D(B)\frac{\partial[B]}{\partial x}, \qquad (10)$$

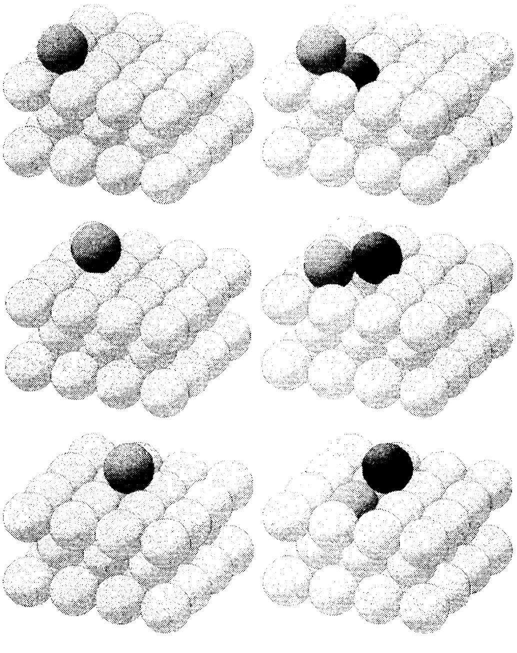
where $J(B)$ is the flux (in one dimension) from diffusion due to a coverage gradient (density gradient in two dimensions) $\partial[B]/\partial x$. Diffusion of surface atoms or molecules at moderate temperatures is an activated process and experimental results are often expressed in the form

$$D(B) = D_0 \exp(-E_m/kT), \qquad (11)$$

where D_0 is the preexponential factor and E_m is the activation energy for diffusion (migration). The energetic barriers to diffusion are usually a small fraction (0.1–0.5) of the activation energy for desorption or sublimation, and so diffusion occurs at much lower temperatures than desorption or sublimation; and many surface species are mobile at room temperature or above. Adatom mobility on semiconductor surfaces is smaller because of the highly directional covalent bonding present that results in nearly equal activation-energy barriers for diffusion and desorption.

Two different microscopic mechanisms for activated diffusion may be distinguished: a hop-site mechanism and a place-exchange mechanism, both illustrated in Fig. 7. In the former, most common situation (necessarily for admolecules) diffusion occurs by the particle hopping from site to site (minima in the surface or adsorption potential energy wells) with a nearly instantaneous transition over an energetic barrier that separates the well minima in two dimensions and normally coming to rest in a new equivalent position one lattice site away. In the second mechanism, atoms insert into interstitial sites, and migration occurs via displacement of an adjacent atom. This involves a local strain deformation of the surrounding atoms along the diffusion path (Kellogg, 1994).

Within the context of the hop-site mechanism, the mean intersite jump frequency Γ may be expressed by absolute rate theory as



(a) (b)

FIG. 7. Two mechanisms for surface diffusion (from top to bottom). (a) Hop-site mechanism. (b) Place exchange mechanism.

$$\Gamma = \frac{kT}{h}\exp\left(\frac{\Delta S_m^\dagger}{k}\right)\exp\left(\frac{-E_m}{kT}\right) \qquad (12)$$

assuming unity transmission coefficient at the barrier, where $\Delta S_m^\dagger$ is the activation entropy and E_m is the intersite activation energy barrier. The diffusion coefficient is related to the jump frequency by $D = a^2\Gamma/2\alpha$, where a is the intersite jump distance and $\alpha = 1$ or 2 for diffusion in one or two dimensions, respectively. Assuming a random walk, the mean square displacement $\langle x^2\rangle^{1/2}$ in time t is given by

$$\langle x^2\rangle^{1/2} = (\Gamma t)^{1/2}a. \qquad (13)$$

The preexponential D_0 in Eq. (11) can be determined from Eqs. (11) and (12) to be $D_0 = \nu a^2/2\alpha$, where ν is the frequency factor in Eq. (12), i.e., $\nu = (kT/h)\exp(\Delta S_m^\dagger/k)$. A rough estimate of the value of D_0 can be made by assuming $\Delta S_m^\dagger = 0$, with $D_0 \approx 2 \times 10^{-3}$ cm^2 s^{-1} for $T = 500$ K, $a = 3$ Å, and $\alpha = 2$. The efficiency of this process also depends on the number of vacancies, in addition to the frequency of jumping to a neighboring vacancy, and so one expects a coverage-dependent value of D_0 in addition to a coverage-dependent value of E_m due to lateral interactions.

Experimental measurements of diffusion mechanisms (including the role of tunneling), diffusion coefficients, and diffusion activation energies on well-defined single-crystal surfaces have now been performed utilizing many different surface spectroscopies. Most of our information on metal-on-metal diffusion has come from observation of individual adatoms using FIM. These studies revealed that $E_m \approx 0.3E_d$. Direct adatom observation can now also be carried out by STM. Surface diffusion of adsorbates has mainly been studied with LITD using coverage-gradient methods in which a sharp boundary between clean and adsorbate-covered regions is formed at low temperatures, and a surface probe is utilized to follow diffusion across the boundary as the temperature is raised. Now, diffusion can also be probed by grating methods utilizing lasers and other structure-sensitive probes like atom scattering.

Diffusion is a dominant mechanism for material transport and can be a rate-determining step in a variety of processes. Reconstructive phase transitions, annealing of surface roughness, segregation, and crystal growth are processes that all involve material (atom, molecule, etc.) transport. In many practical examples, as in polycrystalline materials, diffusion of atoms along grain boundaries occurs simultaneously with diffusion across the lattice, and this complicates the observed kinetics from that discussed above.

3.4 Desorption

Desorption is the removal of adsorbed species from a surface into a free adsorptive phase. Adsorption/desorption equilibrium is established when the desorption rate (always an activated process) is equal to the adsorption rate. Increasing the surface temperature increases the desorption rate by providing more thermal energy (primarily due to phonon coupling with the degrees of freedom of the adsorbate-surface complex) that can be used to overcome the desorption activation energy barrier.

The desorption rate expression can be written in the form

$$r_d = k_d \theta^n, \tag{14}$$

where k_d is the desorption rate constant, usually given by an Arrhenius expression $k_d = \nu_n \exp(-E_d/RT)$, θ is the surface coverage of desorbing species, and n is the kinetic order of the desorption reaction. For sublimation of multilayer films, $n = 0$, while $n = 1$ for atomic or molecular desorption from an adsorbed monolayer, and $n = 2$ for desorption processes where bimolecular recombination at the surface occurs prior to desorption. The desorption activation energy E_d often shows strongly coverage-dependent changes, reflecting lateral interaction effects of adsorbates on adsorption energies. While this expression describes the kinetics of the desorption process, the dynamics of the event is not included. Detailed dynamical information now exists for a variety of desorption processes, and atoms and molecules are often observed to emerge from the surface without being fully equilibrated to the surface temperature. This is manifested by noncosine angular distributions and translational, rotational, and vibrational energy-level populations that do not reflect the surface temperature and are not necessarily described well by Boltzmann distributions. This is especially true for the desorption of the products of exothermic surface reactions.

Temperature-programmed desorption (TPD) or thermal-desorption spectroscopy (TDS), in which the surface temperature is increased linearly with time, is a widely used technique in surface science to determine activation barriers for desorption or surface reaction and binding energies of adsorbates in specific adsorption sites. During the temperature ramp, a mass spectrometer is used to monitor the desorption flux of previously adsorbed species, determining the identity of all desorbing gases and measuring their desorption rates.

Energy can be provided to the adsorbate-surface complex by other (than thermal) means, and this can be used to overcome the activation barrier to desorption. These other excitation mechanisms are more specific in their activation of adsorbed molecules compared to thermal desorption and give rise to

ESD, PSD, ion-induced desorption, and collision-induced desorption.

4. SURFACE REACTIONS

The simplest surface reactions at the gas–solid interface are dissociative chemisorption, in which bonds are broken in the incoming molecule to produce surface-bound atoms, and adatom recombination, in which bonds are made between surface-bound atoms. Surface reactions can be divided into two primary categories. In the first case, the solid surface catalyzes a chemical reaction but does not undergo any net chemical change itself, e.g.,

$$CO(g) + H_2O(g) \xrightarrow{Fe_2O_3 \cdot Cr_2O_3} CO_2(g) + H_2(g). \tag{15}$$

Heterogeneous catalysis relies on this class of reactions to carry out the majority of the processes required for the chemical and petroleum industries. In the second case, the solid surface is directly involved in the reaction by compound formation. Reactions like

$$Ni(s) + CO(g) \rightarrow NiC(s) + NiO(s) \tag{16a}$$

are involved in describing oxidation and corrosion, while reactions like

$$Ni(s) + 4CO(g) \rightarrow Ni(CO)_4(g) \tag{16b}$$

are typical for etching processes. The elementary processes described in Sec. 3 are important for both categories of reactions.

4.1 Heterogeneous Catalysis

Catalysis occurs by the acceleration of the rates of chemical reactions without net consumption of the catalyst and without any influence on the overall reaction thermodynamics (equilibrium balance). Heterogeneous catalysis means that catalyst, reactants, and products involve more than one phase. This is the case for the majority of industrial catalysts, where the catalyst is a solid (surface) and the reactants and products are in gaseous or liquid phases. A catalyst is characterized by its activity—the rate of a catalyzed surface reaction—and its selectivity—the tendency of one desired reaction product to be produced over all others. Dispersion is the term used to define the fraction of total catalyst atoms that are present at the surface. Most catalysts are characterized by a very high dispersion of the active phase to increase the contact area between the catalyst and the reactant/product fluid. In the case of metal-based catalysts, this usually occurs by the formation of small separated crystallites (<20 Å) on a porous, high–surface-area oxide support (which also greatly reduces sintering—the agglomeration of small particles to form a larger one), typically leaving more than 50% of the active catalyst exposed at the surface.

Three major types of catalysts may be distinguished:

1. electronic—oxidation and reduction,
2. acidic—ionic, and
3. structural—molecular sieves.

Oxidation and reduction catalysts usually involve electron transfer to or from the solid surface. Solids with free or easily excited electrons, like transition-metal surfaces (Fe, Pt, Ni) or semiconductors (NiO, ZnO) are likely catalysts. Metal surfaces commonly exhibit spontaneous H_2 and O_2 chemisorption and are the preferred catalysts for (de)hydrogenation, reduction, or oxidation. The activity of catalysts using different transition metals varies over several orders of magnitude, e.g., eight for the hydrogenolysis of ethylene ($CH_2=CH_2 \rightarrow CH_4$). Often this variation is described by a "volcano" plot in which one transition metal is the best (at the top of the volcano) and metals to the left or right in the periodic table have lower activity. Ionic catalysts, like the insulators Al_2O_3 or SiO_2, with acidic functional groups are used for cracking and isomerization (skeletal rearrangements) that occur via carbonium ion mechanisms common in organic chemistry. Shape-selective catalysts, like zeolites, have high internal areas (100–500 m^2/g) and well-defined pore structures with sizes on the order of molecular dimensions. The control exerted by the zeolite on diffusion of reactants and products through the pores significantly alters the overall activity and selectivity from that of the acidic functional groups of the zeolite itself (or of the metal catalyst particles placed into the zeolite cages). Finally, catalysts contain (usually but not always by design) chemical additives that dramatically modify the observed activity and selectivity. These are called promoters or poisons depending on the desirability of their action.

In part, surfaces enhance reaction rates simply on account of dimensionality (adsorbed reactants are confined to movements within two dimensions only). Of course the main effect of a catalyst is to lower rate-limiting energetic barriers due to stabilization of transition states and reaction intermediates, as shown in Fig. 8.

Two main reaction processes are distinguished in heterogeneous catalysis (Adamson, 1990). The Langmuir–Hinshelwood (LH) mechanism

$$A(\text{ads}) + B(\text{ads}) \rightarrow \text{Products} \qquad (17a)$$

involves the reaction of two adsorbed species. A simple reaction rate law can be formulated that is proportional to the surface coverages $\theta(A)$ and $\theta(B)$, and these can be expressed by Langmuir adsorption isotherms. The Eley–Rideal (ER) reaction mechanism

$$A(\text{ads}) + B(\text{gas}) \rightarrow \text{Products} \qquad (17b)$$

takes place as the direct result of a collision between an impinging gas molecule and a molecule adsorbed on the surface. In this case, the rate expression can be given as proportional to the surface coverage $\theta(A)$ and the pressure of B. The occurrence of these two mechanisms in a variety of surface reactions has been debated over the years, with the result that nearly all thermal surface reactions are thought to proceed via a LH mechanism and coadsorbed reactants. However, recently several reactions have been demonstrated in carefully controlled studies to occur via an ER process (Rettner and Auerbach, 1996).

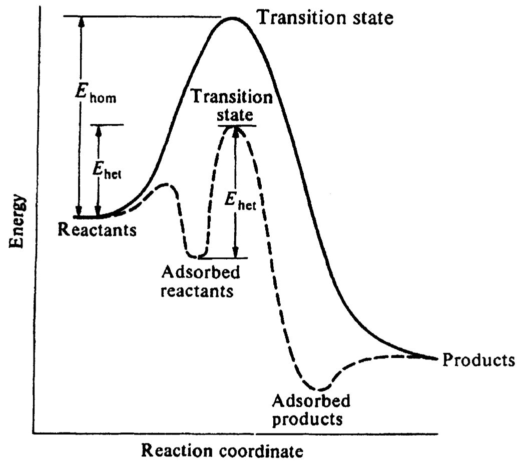


FIG. 8. Schematic representation according to transition-state theory of a homogeneous reaction (solid line) and a heterogeneous reaction (dashed line), illustrating how catalysts increase reaction rates by lowering the energetic barrier to reaction (from Gasser, 1985).

A surface-science approach to catalysis offers the possibility of investigating catalytic surface processes at a molecular level. The most powerful probe of reaction mechanisms is modulated molecular-beam reactive scattering (MBRS), where an incident molecular beam is chopped and the TOF of incident molecules is determined by phase-shift measurements. These time-dependent studies are capable of differentiating between different reaction mechanisms by measuring (through the phase lag) the residence times of reacting molecules on the surface. Model systems have been studied to understand the role of individual reaction steps in the overall activity or selectivity of a given catalyst system. A challenge for current research is to bridge the "pressure gap" that exists between UHV surface-science studies and the high pressures (1–100 atm) of commercial chemical processing. Providing the basic physicochemical foundation for these processes is important for the many catalytic challenges that lie ahead, e.g., the activation of methane (CH_4) to produce useful fuels and chemicals from the vast quantities of CH_4 that are available.

An example that illustrates the interplay between elementary surface processes and their effect on the catalytic reaction mechanism and the observed rate law is the catalytic reaction of NO and CO over Rh. This is a key reaction for control of pollution from engine exhaust gases. One proposed mechanism on Rh(100) surfaces is shown in Table 3 (Hendershot and Hansen, 1986). The rate law shown for the overall reaction is "simple" for a first-order rate-determining step (rds) even though the reaction mechanism is rather complicated. If the dissociation of NO (step 3) is the slow step, then it is straightforward to derive the LH rate law given.

Table 3. Mechanism of the NO + CO reaction on Rh(100) surfaces. Overall rate is

$$r = \frac{d[\mathrm{CO_2}]}{dt} = \frac{k_3K_2p(\mathrm{CO})}{1 + K_1p(\mathrm{CO}) + K_2p(\mathrm{NO})}.$$

	Reaction	Rate constant
(1)	CO(gas) ↔ CO(ads)	K_1
(2)	NO(gas) ↔ NO(ads)	K_2
(3)	NO(ads) → N(ads) + O(ads)	k_3 (rds)
(4)	2N(ads) → N_2(gas)	k_4
(5)	CO(ads) + O(ads) → CO_2(gas)	k_5

Surface-science studies have elucidated a detailed reaction mechanism for the NH_3 synthesis reaction (Ertl, 1983), as shown in Fig. 9. The reactants N_2 and H_2 chemisorb on the Fe surface, surface intermediates are formed that sequentially hydrogenate to form NH_3, and the products desorb and free the Fe surface for further reaction. In this case, the catalyst greatly speeds up the reaction via lowering the barrier to the dissociation of dinitrogen (bond dissociation enthalpy = 945 kJ/mol or 226 kcal/mol) in the gas phase by forming stable Fe–N bonds for adsorbed nitrogen adatoms.

4.2 Oxidation and Corrosion

Topologically, the growth of surface oxide films involves elementary reactions at the oxide/adlayer interface, inside the oxide layer, and at the metal/oxide interface. In the oxidation of metals, the oxygen-containing molecule (typically O_2) first has to chemisorb dissociatively on the surface. Adsorbed oxygen may then migrate on the surface in the form of a polarized or charged adparticle, may occupy a subsurface site, or may diffuse into the crystal. Rearrangement of surface atoms occurs with dissolution of oxygen into the near-surface region, and oxide islands nucleate, grow laterally, and eventually coalesce to produce a continuous oxide film. Growth of surface oxide films is dependent on the diffusion of cations, anions, and electrons through the oxide layer. Already in 1949, Cabrera and Mott (1949) developed a mechanism that described the growth kinetics of very thin (10–50 Å) films in which electrons tunnel through the oxide film to produce oxide ions from the oxygen atoms at the surface and induce a large electric field gradient at the surface, which enhances cation diffusion into interstitial sites of the oxide from the metal-oxide interface. Typical rate laws for the film thickness d with oxidation time t show a logarithmic dependence, $d_{ox} = k_1\log(k_2t + k_3)$ (low-T oxidation of Fe), parabolic dependence, $d_{ox}^2 = k_1t + k_2$ (high-T oxidation of Fe), or unimpeded dependence, $d_{ox} = k_1t + k_2$ (light metals, like Na, Ca, Mg).

Many other oxidation reactions involving halogens, chalcogenides, and carbon-containing molecules proceed to form surface compounds on solids. Examples include the formation of metal chlorides, sulfides, and carbides following chemisorption of Cl_2, H_2S, and CO, respectively, the conversion of CuO catalysts to $CuCl_2$ upon exposure to HCl, and the formation of volatile fluorides of Si following exposure to XeF_2 (etching).

Corrosion reactions on metals are extensive oxidation processes consuming large amounts of the metal, and corrosion often refers to the loss of material from the solid due to dissolution or flaking of the oxidation products at the surface. Corrosion is an elec-

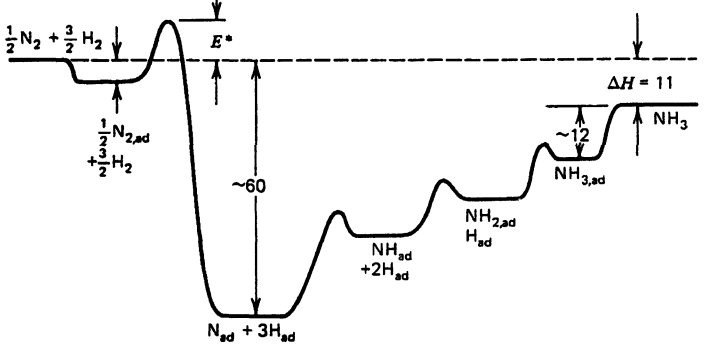

FIG. 9. Potential-energy diagram showing the thermochemistry of catalytic NH_3 synthesis over Fe surfaces. The activation energy E^* for the rate-limiting reaction step actually depends on the Fe surface structure and the amount of adsorbates (coverage) on the surface. Energies are given in kcal/mol. (From Ertl, 1983.)

trochemical process, as shown in Fig. 10, where O_2 and liquid water are depicted as essential ingredients for the rusting of iron. In some cases, the oxidation products may themselves offer corrosion protection. The oxidation of aluminum alloys, extensively used in aerospace, commercial, and semiconductor industries, produces a 20 Å film of Al_2O_3, which forms a protective coating against further oxidation below 400 °C. Stainless steels, known for their high strength and superior workability, obtain their corrosion resistance by the formation of a thin passivating oxide layer of Cr_2O_3. In most cases, however, corrosion inhibition is achieved by added adsorbates, such as in the use of imidazoles to inhibit copper corrosion, or by dense polymeric protective films (paints and coatings).

5. DEPOSITION AND SURFACE PROCESSING

Deposition and surface modification processes are used extensively in the semiconductor industry for the production of solid-state microelectronic devices. In this section we briefly describe atomic processes occurring during crystal growth, focusing on nucleation and growth mechanisms in deposition processes for the production of epitaxial thin films, and comment on important applications in etching, lithography, and the emerging field of nanotechnology. The interested reader is referred to the book by Sze (1988), in particular to the chapters on epitaxy by Pearce, etching by Schutz, and lithography by Watts.

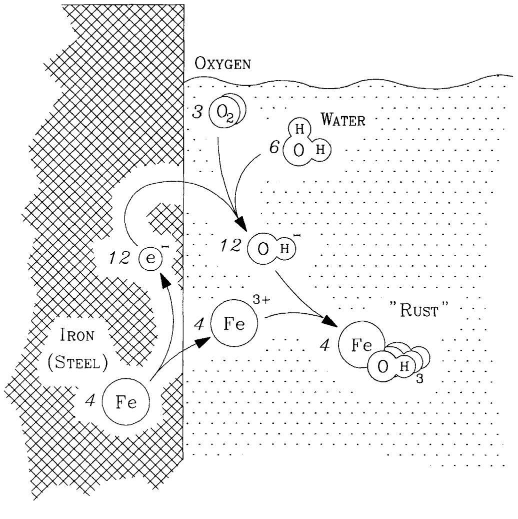

FIG. 10. The oxidation of Fe produces Fe ions and electrons that are then combined with oxygen and water at the cathode to form $(OH)^-$ ions. Rust formation occurs due to recombination of Fe^{3+} and OH^- ions that can be formed if water and oxygen are present simultaneously.

5.1 Nucleation

Nucleation is the formation of very small particles of a new phase due to random fluctuations in the density. Particles larger than a critical particle size tend to grow, and those below it tend to dissolve. The critical size balances the free energy of formation of the particle and the surface free energy of the particle, and particles greater than the critical size tend to grow because the surface-to-volume ratio decreases with increasing particle size. In nucleation on surfaces under nonequilibrium conditions (which is usual), the nature of the surface plays a significant role. The critical particle size then depends on the adsorption, diffusion, and interaction parameters of the particular system. In the case of adparticles on a surface, at high $\Delta\mu$ (chemical potential difference, or thermodynamic driving force), extreme values of the critical particle size i are $i = 1$, i.e., adatoms only have to meet each other, and $i = 0$ in the case of defective surfaces, i.e., adatoms "just" have to occupy a special adsorption site to initiate growth. Flat surfaces have different nucleation rates than stepped surfaces. In the absence of island nucleation the condensation coefficient is a function of the step density. At low $\Delta\mu$ growth does not occur at a measurable rate on flat surfaces but is mediated by screw dislocations.

With the aid of STM, and the related technique atomic force microscopy (AFM), it is now possible to monitor nucleation at an atomic scale in the vapor deposition of thin films. Systematic investigations with atomic resolution of the adsorption of atoms and nucleation on "perfectly" flat terraces and studies of the influence of step structures, defect structures, impurities or coadsorbed particles, temperature, and incident flux have allowed new insight into nucleation phenomena.

A sketch of atomistic processes responsible for nucleation and growth of thin films on a solid substrate is shown in Fig. 11 (Venables, 1994). Particles from a dilute gaseous phase arrive at the surface with a rate r to form adatoms. Their mean displacement x from their arrival site during their residence time on the surface, τ, i.e., prior to evaporation, will depend on the kinetic parameters of diffusion and desorption and may be written as

$$x = (D\tau)^{1/2} = a\left(\frac{\nu_m}{\nu_d}\right)^{1/2} \exp\left(\frac{E_d - E_m}{2kT}\right), \qquad (18)$$

where D is the diffusion coefficient, a is the jump distance, and ν_m and ν_d are the frequency factors and E_m and E_d the activation energies for diffusion and desorption, respectively. Since typically $E_d \approx 3E_m$, x/a can be large at suitably low temperatures, and this allows the adatom to encounter specific sites and other adatom structures to which it might bind before re-evaporation. Critical factors affecting the concentration of nucleated clusters are the density of adatoms on the surface and the binding energy between two atoms.

5.2 Growth Mechanisms

Three different growth modes for the deposition of material A on a substrate B are distinguished as shown in Fig. 12:

1. a perfect layer-by-layer growth, Frank–van der Merwe (FM);
2. 3D growth directly ontop of the substrate, Volmer-Weber (VW); and
3. a combined growth where the first layer(s) grow(s) in two dimensions and every subsequent layer in three dimensions—Stranski-Krastanov (SK).

These growth behaviors can be rationalized in terms of a simple thermodynamic model that takes into account the relative surface free energies γ_A and γ_B, the free energy of the overlayer–substrate interface γ_{AB}, and the crystallographic misfit between the deposit and the underlying substrate surface. If γ_A +

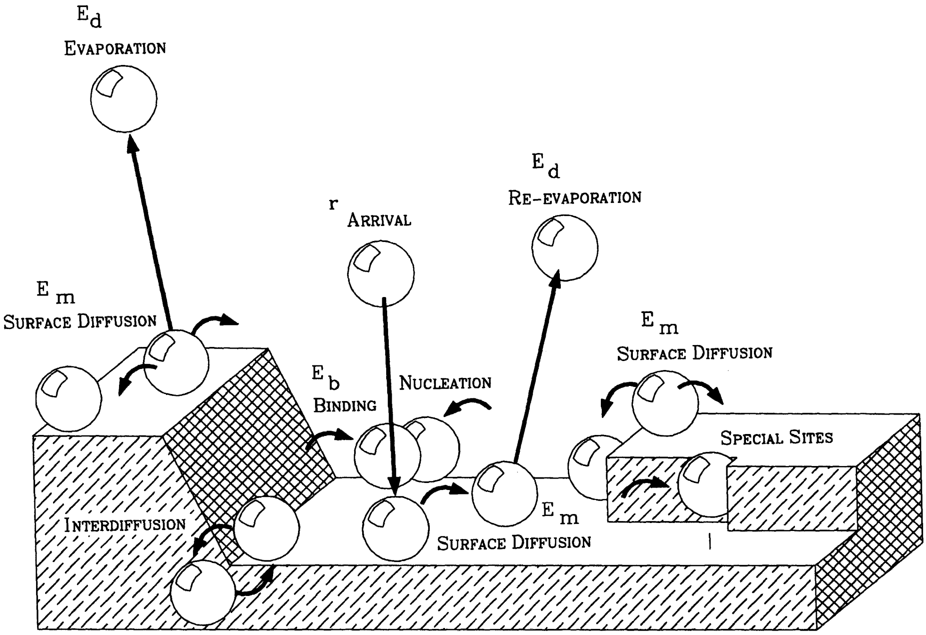

FIG. 11. Schematic diagram of key processes controlling nucleation and growth on surfaces, highlighting the importance of the rate of arrival r of species to the surface and the activation energy barriers for evaporation (desorption) E_d, diffusion E_m, and binding E_b (after Venables, 1994).

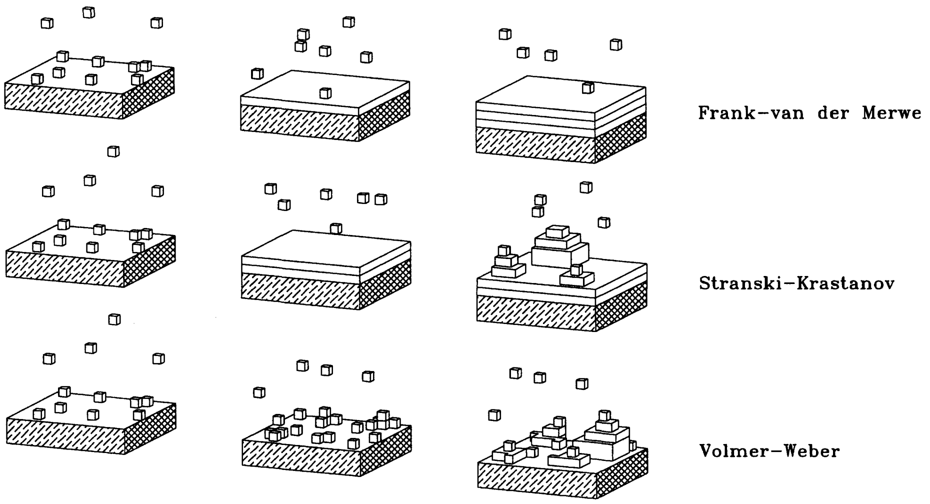

FIG. 12. Schematic view of the three topologically distinct epitaxial growth modes. Growth proceeds from left to right according to each mechanism.

$\gamma_{AB} < \gamma_B$, island growth (VW) is favorable. If $\gamma_B < \gamma_A + \gamma_{AB}$, then B atoms tend to cover the surface completely, and a layer-by-layer growth (FM) is obtained. In the latter case, however, γ_{AB} often increases with the thickness of the layer because of strain in this layer. Beyond a critical layer thickness, island formation is thermodynamically favored, resulting in layer-plus-island growth (SK), a rather common growth mode. Many practical layered structures of technological importance, most notably semiconductor heterostructures and magnetic superlattices of alternating layers (ABAB . . .) of a magnetic metal (Fe, Co, Cr, etc.) and a noble metal (Cu, Ag, etc.) are grown under kinetically limited conditions, i.e., they are far from being equilibrium structures, and so growth modes in these systems cannot be so simply classified.

The 2D and 3D islands formed during growth exhibit a wide variety of structures depending on a complex relationship among all of the parameters affecting nucleation and growth, such as the incident flux, surface temperature, diffusion constants, and so on. Island shapes range from ramified (fractal) structures due to low diffusion mobility along the island edges to polyhedral and triangular structures. Figure 13 illustrates how temperature affects the density and shapes of 2D Si islands grown on the 7×7-Si(111) surface. Stepped (vicinal) surfaces have been shown to exhibit strong anisotropic effects for diffusion along or across the steps, and this strongly affects the shapes of these islands. Reconstructed surfaces with row structures exhibit similar effects.

A detailed description of film growth has to include a kinetic model of the elementary microscopic processes. Theoretical modeling, calculations, and simulations are especially useful since measurement and control of many of the elementary processes are not directly accessible from experiments. In kinetic Monte Carlo simulations (see MONTE CARLO METHODS), atoms are deposited randomly on a well-defined surface and any of the kinetic parameters can be varied to explore their influence on interface structures and growth rates. Using either calculated or model interaction potentials, molecular dynamics calculations (see SIMULATION BY MOLECULAR DYNAMICS) can provide 3D trajectories of individual atoms in large systems of atoms interacting with each other and the surface.

Comparable nucleation and growth mechanisms operate in electrocrystallization of metals on electrodes. In the electrochemical environment a complete monolayer may easily be grown by a process called underpotential deposition (UPD). When the chosen potential is slightly "under" the potential necessary for bulk deposition, e.g., Ag on a

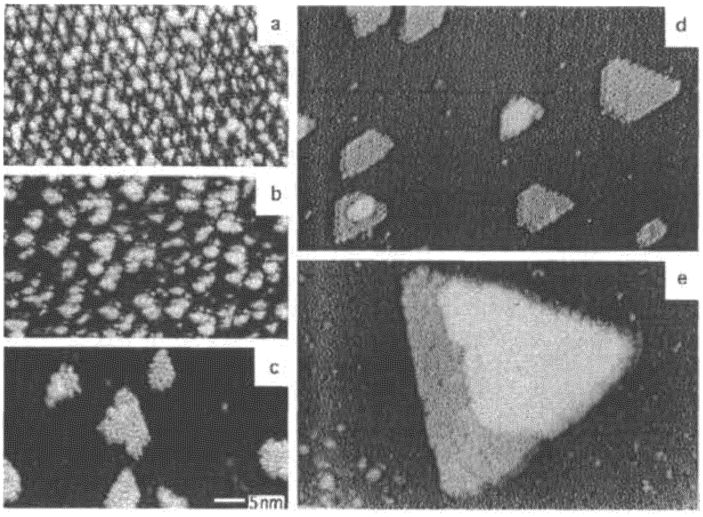

FIG. 13. Sequence of STM images showing the results of nucleation and growth of Si islands on a Si(111) 7 × 7 surface at different substrate temperatures: (a) 20 °C, (b) 250 °C, (c) 350 °C, (d) 450 °C, and (e) 550 °C. On the perfectly triangular island in (e), the second epitaxial layer is visible. (From Köhler *et al.*, 1989.)

Ag electrode, it is possible to deposit a monolayer of Ag on Au but impossible to deposit more Ag at the same potential.

Epitaxy is a special type of growth process where the orientation of the grown film is determined by the single-crystal substrate. A major application for epitaxy is in semiconductor device fabrication. Homoepitaxy means that the grown layer is identical to the single-crystal substrate (e.g., Si on Si, or diamond on diamond) while heteroepitaxy refers to growth of one material on a substrate of another material, and this can be done even when their lattice constants are different (e.g., Si on Ge, or $Al_xGa_{1-x}As$ on GaAs). Heteroepitaxy, in particular, gives the opportunity for modifying electronic and magnetic properties of thin layers with respect to bulk properties. For example, the required high resistivity for high breakdown voltages of transistors simultaneously limited the frequency behavior and power dissipation in the case of the bulk wafers used historically, but the epitaxial growth of a high-resistivity layer on a low-resistivity substrate solved this problem. The strain induced in the film grown in the case of a significant lattice mismatch between the bulk lattices of the film and substrate, however, restricts heteroepitaxy to occur only below a critical thickness.

5.3 Deposition Methods

A wide variety of processes have been used to deposit materials, including those using liquids, ion-beam (sputter) deposition, laser vaporization deposition, molecular-beam epitaxy (*q.v.*) (MBE), and chemical vapor deposition (CVD). Here we can only consider two methods. CVD processes have found widespread application for the preparation of thin films of conducting, semiconducting, and insulating materials needed for the fabrication of integrated circuits. CVD uses gas-phase molecules [precursor gas(es)] that contain the elements required for the deposited materials and is carried out at pressures from 10^{-3} to 760 Torr (1 atm). The precursor gas can be "activated," i.e., made more reactive, photochemically (laser CVD) or by a radio-frequency (rf) or microwave plasma reactor [plasma-enhanced CVD (PECVD), or plasma deposition]. The morphology (crystallinity, defects, impurities, etc.) and the growth rate are found to depend on the substrate, precursor gas, additional reaction gases, etching agents, gas concentration, total pressure, and temperature. For a discussion of the fundamental surface chemistry and kinetics in an exemplary CVD process (W metal deposition using WF_6 and H_2), the reader is referred to Creighton (1994); see also CVD (CHEMICAL VAPOR DEPOSITION).

Some other materials that have been deposited by CVD techniques can be mentioned. The CVD growth of Si epitaxial thin films can be carried out using $SiHCl_3$ and H_2. Silane (SiH_4) and germane (GeH_4) are common precursor gases for thin-film deposition of $Si_{1-x}Ge_x$ heterostructures, while metal carbonyls and organometallic compounds are suitable for the deposition of metal films (Al, Cd, Ni, Fe, etc.). Polycrystalline Si thin films can be deposited at room temperature by PECVD using SiH_4, SiF_4, and H_2. The crystalline fraction increases significantly with addition of SiF_4, indicating the role of etching agents that preferentially remove amorphous material. Low-pressure synthesis of diamond can also be carried out with a variety of molecules as carbon sources in CVD. One possible layout of a PECVD system for diamond growth consists of a parallel-plate rf plasma reactor operated with methanol, a hydrogen radical source using a microwave discharge for the etching of nondiamond carbon phases, and a laser for substrate heating.

MBE is essentially a highly controlled evaporation process that occurs in UHV. MBE has a number of inherent advantages over CVD techniques. Its main advantage for growing thin films is low-temperature processing, which minimizes unintentional diffusion processes. This is especially important for the growth of quantum wells and quantum wires, which are made from ultrathin-layer structures that generate electron-confining potential wells on such a small scale that particle-in-a-box electronic quantum states are produced. For example, the growth of AlGaAs on vicinal (110) GaAs surfaces forming quantum wires along the step edges can be accomplished with MBE techniques. Other advantages include precise control of doping, allowing the generation of complicated doping profiles in semiconductors, and the ability to monitor film growth and the quality of a growing layer *in situ* by RHEED. The main technological disadvantages of MBE compared to CVD are its low growth rates and its expense.

5.4 Etching

Etching is the process of removing surface material and thus, like dissolution, is the opposite of crystal growth. Etching is widely used for surface treatments and as a fundamental step in semiconductor processing. For example, wet chemical etching using HF, HCl, or sulfuric acid (H_2SO_4) in combination with passivation and rinse treatments can produce very flat surfaces with subnanometer surface undulation for Si and GaAs surfaces. Various techniques depending on the substrate and the desired etching results have been developed. In all of these techniques, corrosive surface reactions occur by breaking chemical bonds within the substrate surface layer by attack of highly reactive chemical species and/or by momentum transfer. A complete microscopic description of the elementary mechanisms remains elusive because etching occurs in very complex environments that are difficult to probe. For example, etching with a reactive plasma (see PLASMA ETCHING) involves a variety of neutral and ionic species and collision, dissociation, recombination, and interaction processes both in the gas-phase plasma and on the exposed surfaces. Processing with nanoscale dimensions requires an improved understanding and new methodology.

The majority of etching methods can be grouped under the heading reactive plasma etching, e.g., reactive ion etching (RIE), reactive ion-beam etching (RIBE), and microwave plasma etching. In such processes, a plasma discharge generates ions and many other chemically active neutral species. Fluorine and chlorine plasmas contain atomic fluorine and chlorine, respectively, which are far more chemically active than the naturally occurring molecular species. In the special case of fluorine etching of Si, atomic F and molecular F_2 etch Si spontaneously at room temperature without a plasma. This can occur through efficient fluorine adsorption and subsequent desorption of volatile SiF_4. When ions strike the surface an increased etch rate is observed, which is not simply due to the additional sputtering effect, in a reaction usually referred to as ion-enhanced etching. Increased surface roughness and synergistic effects during desorption have been discussed as possible causes. In the etching of Si with a plasma using Cl_2, chlorine adsorption produces a surface $SiCl_2$ species that is a precursor to the formation of volatile $SiCl_4$. In contrast to F_2, Cl_2 does not etch Si spontaneously, and so this type of reaction is termed ion-induced etching because it occurs only in the presence of ion bombardment.

Isotropic etching during pattern transfer in lithography (see below) usually results in "undercutting" of the mask, which narrows the feature. This is a major problem for linewidths and spaces of features that are significantly smaller than the feature height, and production of these structures requires an anisotropic etching. Wet etching is isotropic, but ion-enhanced processes are expected to produce anisotropic etching with some degree of mask undercutting, and ion-induced processes should produce perfectly anisotropic etching in the vertical direction.

5.5 Lithography and Nanotechnology

The manufacturing of integrated circuits requires sequential formation of patterned layers of material on a substrate surface, most commonly a Si wafer. These layers alternate between insulators, semiconductors, and conductors, and the intricate pattern that will eventually be in the respective layers is first defined in a polymeric resist film via lithography and then transferred to the layer usually with etching techniques (see MICROLITHOGRAPHY). Historically lithography started out as photolithography, where an image is recorded into a resist (an etching-proof material) by means of light exposure to chromic groups. The resulting changes are then responsible for a different solubility or volatility of those parts compared to the unexposed areas in a subsequent treatment called resist development. In modern microlithography, optical methods are complemented by electron, x-ray, and ion techniques, each with particular advantages. In x-ray lithography, x rays are used to minimize diffraction limitations during the writing process. It is not surprising that the masks themselves are produced by x-ray microlithography. The basic structure of these masks is an adsorber film (Ta,W,Re) on top of a membrane (Si, SiN, SiC, diamond) that is transparent for soft x rays. Figure 14 shows the basic fabrication process of a Ta/SiN mask used for x-ray lithography illustrating how several different deposition and etching methods are needed to construct such a structure. Novel approaches for the

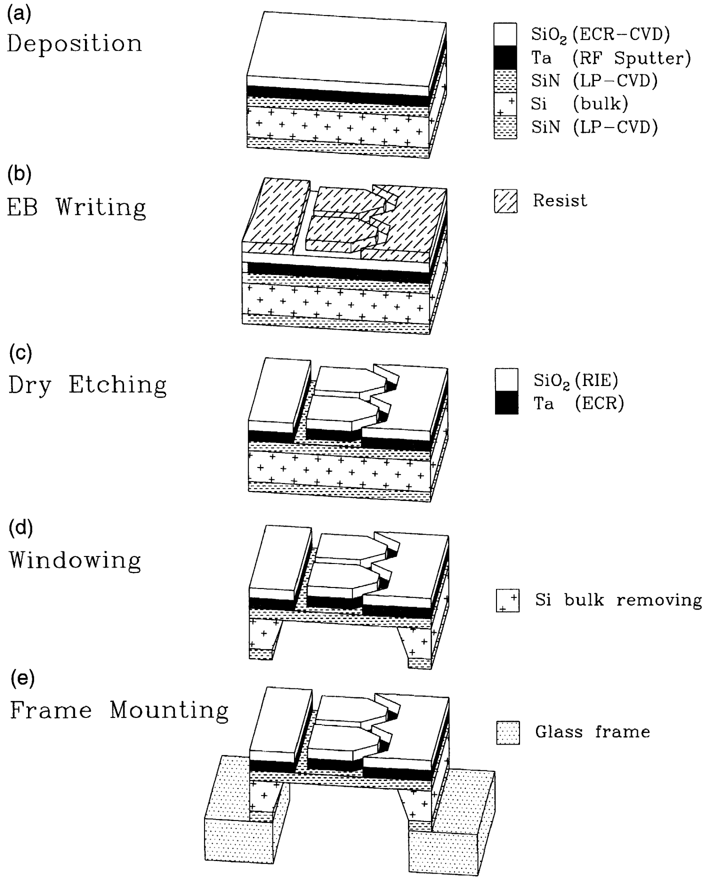

FIG. 14. Fabrication steps in producing a Ta/SiN mask starting with a 3-in. Si wafer as the base material. (a) Deposition of 2-mm-thick SiN films via low-pressure CVD (LPCVD), a 0.7-mm-thick Ta film by rf sputtering a Ta target onto the substrate, and a SiO_2 etching mask via electron cyclotron resonance CVD (ECR-CVD). (b) Resist pattern production by electron-beam writing following deposition of the resist film. (c) SiO_2 etching in regions not protected by the resist film using RIE and Ta film etching in regions unprotected by the SiO_2 mask using ECR followed by removal of the resist film. (d) Underside etching of SiN by using RIE and bulk Si removal using an alkaline solution in a "wet chemical" procedure. (e) Mounting on a glass frame. (After Oda and Yoshihara, 1993.)

formation of nanostructures (with dimensions of nanometers) utilize STM or AFM.

Realization of the fantastic promises of nanotechnology—whereby nanoscopic devices are constructed at the atomic or molecular level, biomolecular modification is carried out with bond specificity by direct manipulation of the atoms of the molecule by cell-repairing nanorobots, and the evolution of ultrafast and ultrasmall computers, smart materials, and self-replicating machines occurs—obviously requires extensions of scanning probe microscopy beyond imaging and lithographic patterning. The most impressive results in direct manipulation of atomic structures have been achieved by using STMs. STM techniques have been extended from positioning individual xenon atoms on a cold (4 K) nickel substrate at 0.5-nm resolution, as demonstrated in the pioneering work of Eigler and Schweizer (1990) who spelled IBM by direct placement of 35 Xe atoms, to the construction with an STM of a "quantum corral" for electrons by placing 65 Fe atoms in a ring about a center atom on a Cu surface (Crommie *et al.*, 1993). The atoms in these experiments were attached to and detached from the STM tip electrostatically by controlling the tip bias voltage. Molecular manipulation has recently been demonstrated in the controlled movement of individual tetrabutylphenyl porphyrins on Si at room temperature. In these studies the STM tip was used to "push" the molecules across the surface. Movement of larger structures such as metal discs and colloidal particles can also now be accomplished by contact AFM and imaged by noncontact AFM. AFM is a scanning probe microscopy technique that relies on surface forces to cause a displacement of a microscopic lever to produce an image. In contact AFM, the lever "touches" the surface and senses the repulsive potential, while in noncontact AFM the lever oscillates just above the surface sensing the attractive potential. Scanning probe technology is therefore capable of enough spatial resolution for both placing and sensing atomic-scale elements on surfaces, but further developments will require increased understanding and control of surface forces.

6. MECHANICAL PROCESSES

Interfaces strongly affect the mechanical properties of polycrystalline materials. These properties define the response of materials to external and internal forces. Deformation phenomena like flow and creep (continuous deformations at constant load) are influenced by interfaces, and surface forces play a role in understanding these distortions. The reader is referred to Sutton and Balluffi (1995) for an in-depth discussion of this topic. Friction, lubrication, and adhesion are important mechanical processes that involve surfaces and adsorbed layers and that are controlled by surface forces. Below we highlight the changes that occur when new interfaces are created as an adherent film is peeled away from a substrate and when two solid objects slide over each other with and without lubricating layers.

6.1 Adhesion

The work necessary to separate two phases A and B with a common interface is known as the work of adhesion W_{AB} between the two phases and is given (most simply) by

$$W_{AB} = \gamma_A + \gamma_B - \gamma_{AB}. \tag{19}$$

An analogous expression for the energy of adhesion can be given, although these equations ignore important electrostatic contributions that can occur due to charging of the surfaces upon separation. In the cases of strong chemical bonding at the interface, these energies are large and can exceed the cohesive energies of the pure phases (i.e., adhesive joints can fail by formation of an interface within the bulk of one of the two phases). This is often desirable since this corresponds to the maximum strength of an adhesive joint. "Peel tests" commonly reveal that failing loads of joints do not approach this value. In these tests, the normal force to separate the joint (tensile strength) is measured, but alternatively one can also determine the force parallel to the surface that is needed to break the joint (shear strength). The simplest model for adhesive joint failure is a classical mechanical picture based on the work of crack propagation and stored elastic energy. However, more detailed models attempt to account accurately for the structural distortions of the surface layers, adsorbate layers at the interface, and the actual bonding interactions present at the interface.

Monolayer or even submonolayer

amounts of adsorbates present at the interface can dramatically influence adhesion, either positively or negatively. Adhesion promoters such as amines for Cu/CuO localize at the interface for a beneficial effect. Segregation of extremely small (ppm) concentrations of impurities (e.g., C, O, S, P, As) in steels and other alloys to interfaces negatively affect adhesion (and can cause bulk material failure when grain boundaries of the pure component are decorated). Polymer–metal interfaces have a great importance, and current research is involved in investigating deposition of metals at polymer surfaces at the monolayer level with surface-science techniques to probe the nature of the chemical bonds at the interface. Reactive processing (e.g., plasma etching) of polymers can break chemical bonds at the interface, generating reactive sites that can form new strong bonds to a second phase.

6.2 Friction and Lubrication

Given the tremendous practical and economic importance of friction (and the related wear), it is somewhat remarkable that so little is known about the microscopic-level processes responsible. However, within the last few years, experimental capabilities for studying sliding friction and wear (in the field of tribology, *q.v.*) have been rapidly advancing. For example, it is now possible to directly measure forces between macroscopic objects using crossed cylinders coated with mica (which can be atomically smooth). Using AFM, one can probe atom–atom forces and friction and sliding friction on atomically smooth, well-characterized surfaces with lubrication films of a known and controllable thickness (within a few angstroms).

Even smooth-appearing surfaces have irregular shapes at an atomic level, and these defects control the nature of contact between two solid surfaces. Understanding the tremendous forces and high temperatures generated at these localized contacts (making and breaking chemical bonds) is necessary for a description of macroscopic friction. This involves the influence of shearing and plowing phenomena within the context of deformations and plastic flow at the atomic level. A phenomenon that has been demonstrated amply at surfaces and measured directly by using an AFM is stick-slip friction motion.

Lubrication is used to decrease the friction between two surfaces. Two types of lubrication are recognized: boundary lubrication and hydrodynamic lubrication. In hydrodynamic lubrication, where the lubricating film is thick enough so that the surface regions are essentially independent of each other, the coefficient of friction depends on the hydrodynamic properties (mainly the viscosity) of the lubricant and not much on the surfaces involved. The specific nature of the solid surface is important in boundary lubrication, which describes the situation for high loads and low speeds where very thin (indeed monolayer) films are present at the sliding surfaces. Understanding this situation requires consideration of the structure, orientation, and bonding of the adsorbed layer at the surface, surface diffusion mobility, and the influence of large mechanical compressive forces on this layer. Modern surface-science tribology research is aimed at developing lubricants that strongly bond to the solid surface but have minimal chemical interactions with other lubricant molecules present on the other solid surface.

7. COMPLEX SURFACES AND ENVIRONMENTS

Many technologically important or fundamentally interesting interfaces are very difficult to study, and thus relatively little molecular-level information is known about surface processes in these systems. In this section, we briefly highlight four examples of these "complex" surfaces and environments to illustrate the wide range of applications for interfacial phenomena. Complex surfaces include those for amorphous materials, which have an irregular structure; porous materials, which have "internal" surfaces; polymer and biomembrane surfaces, which have a complicated morphology; and very heterogeneous surfaces with a multiplicity of surface species. Complex environments mainly mean those that are not compatible with the UHV conditions required by many surface analytical techniques: liquid solutions such as those in electrochemical devices and fuel cells, "wet" solids such as biological samples, high–vapor-pressure materials, and high-pressure catalytic reactors. We also include outer space, which exposes surfaces to vacuum and bombardment by a myriad of particles.

7.1 Amorphous and Porous Materials

Amorphous materials are often used for their chemical or heat resistance, electrical isolation, and spectral transmission properties. The most common amorphous materials are glasses (supercooled liquids). Amorphous means literally "without shape," and so these materials do not exhibit the regular, well-defined atomic arrangement of crystalline solids. The irregular surface structure is not accessible via diffraction measurements. Adsorption and reaction at the surface can be studied by AES, XPS, and SIMS, which are all methods that do not rely on long-range order of the substrate. If the sample is an electrical insulator, charging of the surface limits analysis. SEXAFS probes only local atomic order and is suitable for studies of these surfaces. Also, Raman spectroscopy with its ability to fingerprint oxide phonon modes provides near-surface information on very thin films. Theoretical calculations for amorphous surfaces are more difficult than for crystalline materials since they have to include a higher number of independent particles and interactions.

Porous materials consist of extensive channels or pores that allow the accessible solid surface area to exceed greatly the geometrical or apparent area. The high activity required for most catalytic conversion processes necessitates the use of porous materials with a high surface area. Oxides such as V_2O_5, Al_2O_3, SiO_2, and TiO_2 are often used directly and catalyze many reactions. When metal-based catalysts are needed, the transition metal (e.g., Ni, Pd, Pt) is placed as a highly dispersed phase of small nanoparticles on high–surface-area oxide supports. Zeolites, inorganic molecular cage structures as illustrated in Fig. 15, are very important as acid catalysts, catalyst supports, and filtration/separation media.

Microporous materials are used as ion-exchange membranes. In applications such as dialysis, the membrane surface has large open pores with diameters of around 300 nm and a system of connected pores in the membrane volume with diameters in the 10–100-nm range. The filtration/separation properties are governed by the pore-size distribution of the membrane surface and volume. Membrane surface charges and the surface pore sizes influence the adhesion properties of molecules. The use of macroporous polymeric media provides extensive control of the surface chemistry that determines the separation selectivity and capacity via the incorporation of specific functional groups that modify the hydrophilicity and chemical affinity in the large and small pores.

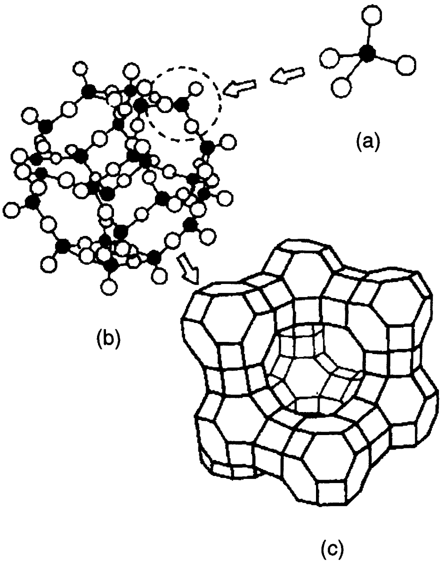

FIG. 15. Structural units showing the framework of a zeolite (faujasite) that gives rise to channels with molecular dimensions permeating the solid. (a) The tetrahedral arrangement of Si (or Al) atoms bonded to O atoms to form (b) a sodalite unit consisting of 24 SiO_4^- and AlO_4^- tetrahedra that are connected in this case to (c) the zeolite superstructure. (From Sleight, 1980.)

Most surface analytical probes only detect external surfaces and not the internal surfaces of the pores, which are relevant. High surface-to-volume ratios for these high–surface-area materials mean, however, that traditional bulk analytical methods such as FTIR and Raman spectroscopy can be used nicely to probe adsorption and chemical changes in the surface layers. The surface area may be determined by measurement of the BET isotherm, and the pore-size distribution may be determined with SEM or mercury porosimetry.

7.2 Polymers and Biological Materials

Plastics, synthetic elastomers (rubber), and thermosetting resins are composed of polymers. The use of these materials is extremely widespread and varied, with new applications being developed continuously. Even though interfacial chemical bonding and structure controls adhesion, thermal stability, and many of the other materials properties, our understanding of surface structure and processes on these materials is relatively poor. They are often amorphous, porous, and nonconductive and have large cross sections for electron- and ion-induced damage, and thus they are quite difficult to analyze by standard surface analytical techniques. XPS has found the most extensive use in identifying functional groups at the surface and studying their reactivity. SIMS also is valuable. FTIR and Raman spectroscopy sample the first few microns of the substrate to provide unique information on morphology (e.g., chain conformation, crystallinity, and orientation). AFM is just beginning to be applied to polymeric surfaces.

Investigations of surfaces of biological samples are a major challenge in terms of finding appropriate preparation and analysis methods. The presence of water inherent to biological systems represents a problem for standard UHV analysis. Below 120 K, however, the partial pressure of water is negligible, and biological samples have been investigated with electron microscopy, SIMS, and XPS under UHV conditions using a cryogenic sample-transfer system.

Surface structure and molecule–solid interactions play important roles in processes on biological membranes. A lipid bilayer structure with hydrophilic functional groups on the outside and hydrophobic functional groups inside represents the basic element of a biological membrane (Fig. 16). The specific binding of large molecules, such as proteins, to the membrane is generally affected by the proximity of polar areas, while the nonspecific adsorption is governed largely by the number of defects and by the availability of hydrophobic binding sites in the interfacial region. Knowledge of these interactions can be used to design artificial lipid membranes with desirable surface properties. A parallel approach uses monomers to insert specific functional groups at the surface of thin polymer films as membrane models. These efforts may ultimately lead to an improved understanding of the molecular recognition of proteins, which controls biological processes like protein separation, biosensing, or drug delivery. TOF-SIMS (for high-molecular-weight capability), XPS measurements, and vibrational spectroscopies are commonly used in these studies. Dramatically increased modeling capabilities are now emerging from improved theory and simulation methods and the enormous increase in availability and speed of computers.

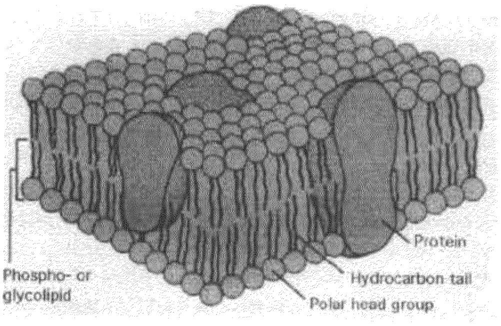

FIG. 16. Illustration of a simple bilayer membrane (from Fendler, 1984).

7.3 Electrochemistry and Fuel Cells

Electrochemical devices convert chemical energy to electrical energy and vice versa. The classical example for an electrochemical process is the electrolysis of water, where water molecules are decomposed by means of a direct electric current. Electrochemical methods are routinely applied in surface treatments such as HF etching of Si samples or for plating purposes, e.g., Pd electrodeposition for electrical contacts. Both neutral molecules and charged molecular species (ions) are important in these processes. Classical investigation methods, such as cyclic voltammetry or polarography (*q.v.*) are used to reveal information on net charge transfers at electrode surfaces. Features in the curves of current versus potential (*I*/*V*) are produced by oxidation, reduction, and capacitive currents and have often been interpreted in terms of surface roughness and morphology without access to the detailed microscopic structure of the electrode interface.

With the development of surface-sensitive optical spectroscopic techniques such as reflection FTIR, SHG, SFG, and XSW, a molecular-level characterization is now possible *in situ*. Also, STM yields images of surfaces with atomic resolution in the liquid, electrochemical environment. Other studies of the electrode surface with AES, XPS, and SIMS via *ex situ* analysis in UHV use an integrated experimental setup that combines the electrochemical cell with a UHV analytical chamber and sample transfer from one environment to the other without exposure to air. This equipment may be used for either UHV surface characterization of a "real" electrode surface or an *in situ* performance test of a model electrode surface that has been prepared and characterized under UHV conditions prior to use.

A primary interest is to describe the electrode–solution interface, i.e., the details of the charge separation responsible for the potential difference at the interface. Figure 17 shows the simplest model for this interface, treating it as an electric double layer, and current research attempts to improve this model. Advances are now being made concerning the relationship between macroscopic kinetic parameters of electrochemical processes and the structural dynamics on a nanometer scale. Chemisorption issues control the nature of molecular adlayer structures and the deposition of metal atoms on metal surfaces in the electrochemical environment. Thus, in many cases a comparison of the electrochemical adlayer structure to its UHV analog is quite useful. For example, the CO adlayer on a Pt(111) electrode in solution shows a potential-induced phase transition that is very similar to that observed for CO adsorption on a Pt(111) surface in UHV experiments.

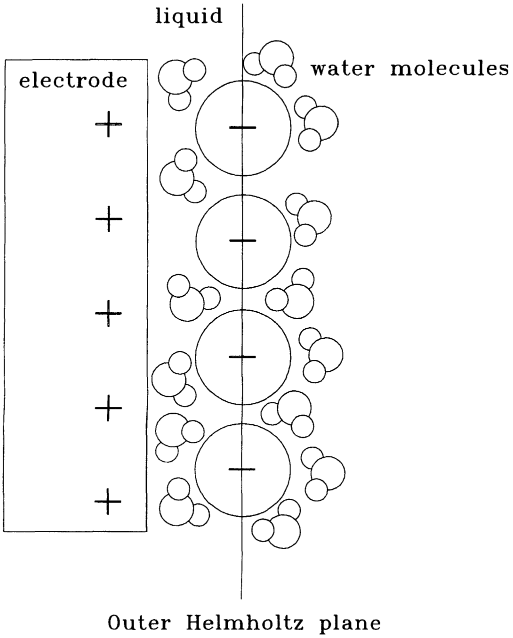

FIG. 17. The simplest model of the electric double layer. The outer Helmholtz plane is due to the ions in the solution, and the inner Helmholtz plane is due to the charge on the electrode. The simplicity of the model arises from the "simple" arrangement of ions and water molecules near the electrode surface.

A fuel cell operates in reverse of electrolysis. The electrodes of a H_2 fuel cell catalyze the controlled oxidation of hydrogen yielding a direct electric current. Fuel cells can utilize other fuels, such as methanol, and have other constructions of solid electrode/liquid electrolyte or solid electrode/solid electrolyte. However, all suffer from limited operation time, which is likely a consequence of surface processes such as an electrolyte-induced surface modification/degradation and poisoning of the electrode surface. Pd and Pt, for example, which are considered as highly efficient catalysts for hydrogen conversion reactions in a low-*p*H environment, also exhibit a strong affinity for CO, which is known to poison the electrode surfaces. Thus, while methanol has some advantages over hydrogen, like its higher energy density, the small amount of CO formed during the reforming process of the methanol poisons the electrodes. The development of CO-tolerant catalysts is of crucial importance for long-term operation of this and several other fuel cells.

7.4 Space Exploration

In high Earth orbit or in outer space, the surfaces of exposed materials undergo collisions with a myriad of energetic particles and are bombarded by intense cosmic radiation, creating a very heterogeneous and complex surface. *In situ* experiments have been performed at NASA's Long Duration Exposure Facility (LDEF) that remained in space for nearly 6 years (Benton *et al.*, 1992), but much of the fundamental interaction physics can be studied in the laboratory under simulated conditions. Atomic oxygen is the dominant atmospheric species in low Earth orbit, and hyperthermal O-atom–surface interactions are central to many materials problems and also account for the nuisance "glow" of the space shuttle. Hyperthermal oxygen sources are used in the laboratory to simulate the kinetic energies of collisions that occur at orbital velocities. Laboratory studies combining FTIR and XPS on the UV degradation of polymer (polyimide) films in air and in vacuum showed that UV irradiation results extensively in surface degradation, leaving the bulk of the polymer intact. Synergistic effects on polymer surfaces were found for UV radiation and oxygen atoms (Hill *et al.*, 1995). While the exposure of fluorinated polyimide films to UV radiation alone caused no observable damage to the polymer surface, atomic oxygen resulted in substantial oxidation of the surface, and a simultaneous exposure to UV radiation caused rapid extensive oxidation. The oxidation process was found to occur via aromatic ring-opening reactions. The effects of hyperthermal (3–7 eV) O atoms, 30-eV O^+, and 30-eV Ne^+ ions on two polymers commonly used for space applications (Kapton and Teflon) have also been investigated with respect to the surface morphology (SEM and AFM) and surface composition (XPS). The damage from its initial atomic-scale roughness (approximately 1 nm) to its final macroscopic-scale roughness (>1 mm) was imaged with AFM (Vered *et al.*, 1994).

Another important consideration in the space environment is the high vacuum that exists. This leads to evaporation and desorption of lubricating layers of water and organic films normally present on all surfaces. Maintenance of good lubrication of moving joints and metal surfaces in contact is essential because the energy gain by eliminating two surfaces with high surface tensions via "vacuum welding" can be very large ($\gamma \approx 150$ kJ/mol, which is comparable to the metal–metal bond strength). In fact, this joining procedure is now used commercially in a variety of bonding applications.

GLOSSARY

Absorption: The penetration of the bulk of one phase by the other in the contact of immiscible phases.

Adsorbate: A species (atom, molecule, radical, or ion) in an adsorbed state.

Adsorptive: A species in a contacting phase that is capable of being adsorbed.

Adsorbent: The surface on which adsorption is occurring. Also called the substrate.

Adspecies: An atom, molecule, or fragment adsorbed on a surface.

Adsorption: Process in which atoms or molecules accumulate (localize) at an interface. A specific location is called an adsorption site. If an energetic barrier has to be surmounted prior to adsorption, the process is denoted as activated adsorption.

Adsorption Complex: The entity constituted by the adsorbate and the part of the adsorbent to which it is bound.

Catalyst: A substance that increases the rate of a chemical reaction without being consumed.

Chemical Vapor Deposition (CVD): Deposition process that proceeds via decomposition of a gaseous species.

Chemisorption (Chemical Adsorption): Adsorption in which the forces responsible for linking the species to the surface are valence forces (covalent, ionic, and dative bonds) similar to those between the atoms in molecules and chemical compounds.

Coadsorption: The simultaneous presence of more than one adspecies.

Corrosion: Material deterioration and removal by chemical reactions.

Deposition: Transferring material from the gas or liquid phase onto a surface.

Desorption: The converse of adsorption.

Diffusion: Large-scale translational displacements of atoms or molecules in a material.

Epitaxy: Growth process where the orientation of a single-crystal layer is determined by that of the single-crystal substrate.

Etching: Removal of surface atoms by reactive particles or chemical reactions.

Implantation: Deposition of foreign atoms deep (microns) into the bulk of a material, usually carried out by high-energy ion bombardment.

Interface: Boundary between two phases; the region of space comprising and adjoining the phase boundary within which the properties of matter are significantly different from the values in the adjoining bulk phases.

Lithography: The transfer of structural information from a template or mask to a substrate by inducing reactions in exposed regions of the substrate using UV light, electrons, ions, or x rays.

Molecular-Beam Epitaxy (MBE): A technique for the vacuum deposition of epitaxial thin films from molecular precursor gases.

Monolayer: Film in which all adsorbed species are in contact with the adsorbent (substrate) surface; i.e., the film has a thickness of one atomic or molecular layer.

Multilayer: Film with a thickness of more than one atomic or molecular layer and thus having not all adsorbed species in contact with the adsorbent surface.

Nucleation: Fluctuation in particle concentration above ambient responsible for initiation of the growth of a new phase.

Phase: A state of matter uniform in chemical composition and physical state throughout.

Photoelectron: Free electron produced by light irradiation in a process denoted as photoelectron emission or photoemission.

Physisorption (Physical Adsorption): Adsorption in which the forces responsible for linking the species to the surface are weak van der Waals forces such as those responsible for imperfections of real gases and condensation of vapors.

Reconstruction: 2D rearrangement of the positions of the surface atoms from those expected for the continuation of the bulk lattice.

Relaxation: Vertical displacement of atomic layers at a surface without significant accompanying horizontal displacements.

Segregation: Movement of one component to an interface resulting in a surface concentration not equal to that in the bulk phase.

Sputtering: Removal of surface material during the impact of energetic particles (usually ions).

Surface: Outermost layer(s) of a condensed phase at an interface.

INTRODUCTION

As is evident from everyday observation, the water surface is macroscopically sharp, clearly separating the bulk water phase from a bulk vapor phase. For many liquids near their triple point, the inhomogeneous, transition region of the surface occurs over a length scale approximately equal to two molecular diameters. However, by adjusting the pressure and temperature to approach the liquid's critical point (e.g., $T = 374.15$ °C and $p = 2.212 \times 10^7$ Pa for water), the surface or interfacial width can be increased substantially to thousands of molecular diameters or larger.

Also evident from macroscopic observations of poking a pin into the water surface is the existence of a surface tension. This tension, when balanced against the gravitational forces, determines the macroscopic behavior of the interface. As an example, water rises when in contact with a vertical wall of clean glass. The shape of the water meniscus is determined by gravity and the interfacial tensions at the glass–liquid, glass–vapor, and liquid–vapor interfaces. The rise indicates that the liquid water is attracted to the glass.

The surface or interfacial tension can be determined by macroscopic measurements, such as the shape of a drop, the rise of a column of liquid in a capillary, or the force on a thin plate dipped in a liquid. This tension is determined by the free energy required to take molecules from the bulk of the liquid and create a unit area of surface or interface (the term interface refers to the transition region between any two bulk phases in contact; the term surface is reserved for the liquid–vapor interface). The energy of a molecule at the surface is altered because it has fewer nearest neighbors than in the bulk. Unless confined or preferentially ordered at the surface, a surface molecule has additional entropy over molecules in the bulk. By use of statistical mechanics the tension can be computed from the variation in density through the interface (the longitudinal density profile). The connection between the interfacial tension and the microscopic density profile can be investigated experimentally and is of fundamental importance.

Multicomponent solutions have interfaces between two bulk liquid phases. For example, a binary mixture consisting of two different chemical components, A and B, can exhibit coexistence behavior of two phases, A^* and B^*, each consisting of primarily one component mixed with a lesser amount of the other component. The interface between these two phases can be described by a longitudinal composition profile whose width is of molecular dimensions far from the mixing critical point. As the critical point is approached, the two bulk phases approach each other in composition, and the interfacial width increases.

The surface or interface does not have to consist of the same components as the bounding bulk phases. Surfactants minimize their free energy by going to the interface and are often found primarily at the interface. Surfactant molecules consist of a hydrophilic moiety (typically a polar group) that prefers to be in contact with a polar solvent, such as water, and a hydrophobic moiety (typically nonpolar) that prefers a nonpolar environment, such as oil or air. An extreme example of this is the formation of monolayers of insoluble surfactants at the air–water interface (denoted Langmuir monolayers). These monolayers have interesting structure in the plane of the surface and exhibit a variety of solid and liquid phases.

Soluble surfactant molecules form a great variety of interfaces internal to the bulk liquids. In a three-component system of oil, water, and a surfactant, the surfactant can partition the water and oil on the microscopic level. For example, random sheets of surfactant separate microscopic regions of oil and water in the bicontinuous microemulsion phase. Additionally, these internal structures and interfaces may be ordered at the interfaces between the bulk phases, thereby influencing the interfacial tension and wetting properties.

Although the structure and properties of liquid interfaces have been studied both theoretically and experimentally for many years, there still remain some fundamental questions that have not been conclusively addressed. For example, the electron and molecular longitudinal density profiles (normal to the interface) and the transverse correlations (within the plane) of the interface are not adequately understood. This is partially due to the theoretical difficulties of understanding inhomogeneous fluid systems. Liquid–liquid and liquid–vapor interfaces can be viewed as model systems whose study will influence our general understanding of inhomogeneous materials. Experimental progress has been impeded by the lack of structural information on the molecular length scale for these interfaces. Until recently, much of the available information was from scattering techniques such as ellipsometry, reflectivity, and dynamic light scattering using wavelengths on the order of those of visible light or longer. The recent application of scattering of shorter-wavelength radiation—in particular, x rays, and also neutrons—has provided detailed microscopic information previously unavailable. It is expected that this rapid recent progress in understanding the structure of liquid interfaces will continue as a greater variety of systems are studied.

This article surveys determinations of structure on the molecular length scale at liquid–liquid and liquid–vapor interfaces. Important phenomena also occur at the liquid–solid interface and are reviewed elsewhere in this Encyclopedia (see SURFACE PROCESSES; SURFACES AND INTERFACES OF SOLIDS, STRUCTURE OF).

1. INTERFACIAL FREE ENERGY AND MACROSCOPIC DESCRIPTIONS OF LIQUID INTERFACES

Josiah W. Gibbs (1957) pioneered the formulation of surface thermodynamics most often used. For a system consisting of two fluid phases separated by an interface, the differential of the Helmholtz free energy F can be written as

$$dF = -SdT - pdV + \sum \mu_i dn_i + \gamma dA, \qquad (1)$$

where S is the entropy, T the temperature, p the pressure, V the volume, μ_i the chemical potential of molecular species i, n_i the number of moles of species i, γ the surface or interfacial tension, and A the interfacial area. Equation (1) supplements the expression for dF of a bulk system by the addition of the last term, γdA. This term represents the free energy required to create a differential area of interface, dA, thereby defining the proportionality constant, the surface or interfacial tension γ, given in units of energy per area. As seen from Eq. (1), the tension γ is given by $\gamma = (\partial F/\partial A)_{T,V,n_i}$. Alternatively, Eq. (1) can be rewritten in terms of the grand canonical potential Ω, where $\Omega = F - \Sigma\mu_i n_i$, resulting in

$$d\Omega = -SdT - pdV - \sum n_i d\mu_i + \gamma dA. \tag{2}$$

This leads to an alternative definition of the tension as $\gamma = (\partial\Omega/\partial A)_{T,V,\mu_i}$.

In Gibbs's formulation, thermodynamic surface functions are described in terms of a mathematical surface, a dividing surface, chosen to be near the macroscopically observable interface and everywhere parallel to it (Fig. 1). Once chosen, the dividing surface determines the volume V^α for each phase α (e.g., $\alpha = 1$ or 2), with the total volume given by $V^{(1)} + V^{(2)} = V$. Far from the dividing surface it is expected that densities of extensive thermodynamic quantities are constant. These quantities can then be written as, for example, $n_i^\alpha = \rho_{i,\mathrm{mol}}^\alpha V^\alpha$, where $\rho_{i,\mathrm{mol}}^\alpha$ is the molar density of component i far from the dividing surface in phase α. When these quantities for the two phases are summed, for example $n_i^{(1)} + n_i^{(2)}$, it is found generally that they are not equal to the total n_i. The remainder is referred to as the surface quantity n_i^s, where $n_i^{(1)} + n_i^{(2)} + n_i^s = n_i$. This is related to the excess or surface density, also known as the adsorption, $\Gamma_i = n_i^s/A$.

For insight into the microscopic nature of excess surface quantities, consider a two-component, two-phase system with a planar interface located at $z = 0$, as shown in Fig. 1. The dividing surface is also chosen to be at $z = 0$. If we assume that within each phase the molar densities are independent of position, that is, constant for $z > 0$ (phase 1) and for $z < 0$ (phase 2), then, in this special case, the sum $n_i^{(1)} + n_i^{(2)}$ is equal to the total n_i. If the molar density profile at the interface is not a step function, i.e., the molar densities of the components near the interface do not abruptly change from one bulk value to the other, but rather change smoothly (see Sec. 2.1), then the surface quantity n_i^s will not usually be zero and may represent a net excess or deficit of component i at the interface (note that n_i^s also depends upon the choice of dividing surface).

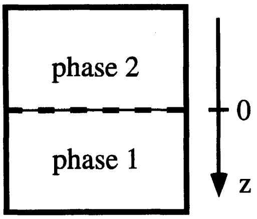

FIG. 1. Cartoon of two-phase liquid system in a jar with an idealized planar interface. The dashed line, directly over the interface, indicates one of many possible locations of the Gibbs dividing surface.

Similar expressions can be written for other extensive quantities such as F and Ω, yielding the surface functions F^s and Ω^s. Under suitable conditions of integration, $F = -pV + \gamma A + \Sigma\mu_i n_i$. The surface Helmholtz free energy F^s is given by $F^s = \gamma A + \Sigma\mu_i n_i^s$, where $F^s + F^{(1)} + F^{(2)} = F$ and F^α for each homogeneous phase can be defined in a manner similar to the definition for n_i^α. If the Gibbs dividing surface is chosen such that $\Sigma\mu_i n_i^s = 0$, then the interfacial tension is given as the interfacial free energy per unit area, $\gamma = F^s/A$. A similar integration of Eq. (2) yields $\Omega = -pV + \gamma A$. The interfacial tension in the grand canonical ensemble is independent of the position of the dividing surface, $\gamma = \Omega^s/A$. A complete discussion of surface thermodynamics is presented by Rowlinson and Widom (1982) and by Defay *et al.* (1966). (Note that the classical thermodynamic arguments do not explicitly include gravity, but assume that it is weak enough not to distort the density gradients across the interface, yet strong enough to produce a stable planar, or otherwise shaped, interface).

Prior to Gibbs's development of interfacial thermodynamics, liquid interfaces were treated as if they were mechanical membranes under tension. Laplace showed that there is a differential pressure Δp across a curved interface. For example, a spherical gas bubble in a liquid would collapse because of the surface tension if the pressure inside was not greater that the pressure outside. The Laplace pressure is given by $\Delta p = \gamma(1/R_1 + 1/R_2)$, where R_1 and R_2 are orthogonal radii of curvature of the interface ($R_1 = R_2 \equiv R$ for the case of the spherical bubble of radius R). Describing interfaces as membranes under tension leads naturally to important relations between interfacial tension and gravity that determine the macroscopic shape of interfaces, thereby allowing for the measurement of interfacial tensions. For example, the capillary rise of a liquid interface in a small-bore cylindrical tube above that of the bulk interface (see Fig. 2) is given by a balance of the hydrostatic pressure determined by gravity and the Laplace pressure. For a bore of sufficiently small radius r, the liquid–vapor (or liquid–liquid) interface in the tube follows the shape of a spherical surface. The surface or interfacial tension between the lower and upper phase is then given in terms of the capillary rise h as $\gamma = \Delta\rho_m ghr/2\cos\theta$, where θ is the contact angle between the lower phase and the capillary wall, g is the gravitational acceleration, $R_1 = R_2 \equiv R = r/\cos\theta$, and $\Delta\rho_m$ is the mass density difference between the upper and lower phases (Adamson, 1990).

The capillary rise can also be determined by noting that the rise of the lower phase results in the replacement of an interface between the capillary wall and the upper phase with that of a wall–lower-phase interface. This can be quantified by using Young's equation that relates the surface tensions at the contact line of a liquid in contact with a solid wall, $\gamma_{sv} = \gamma_{ls} + \gamma_{lv}\cos\theta$, where s, l, and v stand for solid, liquid, and vapor (the upper phase), and θ is the contact angle in Fig. 2. The difference between the interfacial free energies, $\gamma_{sv} - \gamma_{ls}$, can be introduced into the equation for the capillary rise, $h = 2(\gamma_{sv} - \gamma_{ls})/\Delta\rho_m gr$. If it is more favorable for the wall to be in contact with the lower phase ($\gamma_{ls} < \gamma_{sv}$), then the lower phase rises (as is true for capillary rise of a water–vapor interface in a glass capillary). If the opposite is true, as for mercury, then the level of the lower phase in a glass capillary drops below the height of the bulk interface.

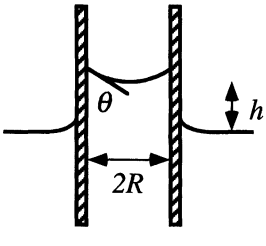

FIG. 2. Capillary rise.

Typical values for liquid–vapor surface tensions are 20–40 mN/m. The water–vapor surface tension of ~72 mN/m at 25 °C is unusually high, though surface tensions for liquid metals are much higher, e.g., ~710 mN/m for the liquid-gallium–vapor interface near 30 °C. The liquid–liquid interfacial tension of *n*-heptane and water is 50.2 mN/m at 20 °C. Addition of a surfactant can reduce the water surface tension by tens of mN/m. At the extreme, the interfacial tensions of liquid–liquid interfaces in oil, water, and amphiphile microemulsion systems have been measured as low as 0.001 mN/m. Tables of values can be found in Bonnet and Pike (1972), Jasper (1972), Weast (1989), and Adamson (1990).

Waves are easily observed on liquid interfaces. A hydrodynamic description of these waves leads to the dispersion relation given by

$$\omega^2 = gq + (\gamma/\Delta\rho_m)q^3, \tag{3}$$

where ω is the frequency, $q = 2\pi/\lambda$ is the wave number (λ, the wavelength) of the surface waves, and g is the gravitational acceleration (Barber and Loudon, 1989). Gravity and surface tension have an equal influence on the surface waves for $q_x = (\Delta\rho_m g/\gamma)^{1/2} \equiv 2^{1/2}/a$ (where a is the capillary constant) or, equivalently, for $\lambda_x = 2\pi/q_x$. For the water surface at 0 °C, $a = 3.93$ mm and $\lambda_x \cong 17$ mm. For surface waves of wavelength $\lambda \ll \lambda_x$ (denoted capillary waves), the frequency is determined primarily by surface tension, while for wavelengths $\lambda \gg \lambda_x$ (denoted gravity waves), gravity dominates. The full treatment of the hydrodynamics of liquid interfaces relies on solutions of the Navier–Stokes equation and is beyond the scope of this article (Landau and Lifshitz, 1986).

These three descriptions of liquid interfaces (classical thermodynamic, mechanical membrane, and hydrodynamic) are adequate to describe most macroscopic behavior. To venture beyond this to describe the microscopic structure requires the use of statistical thermodynamics and new experimental methods capable of probing on the molecular length scale. The study of the density variation when passing from one bulk phase through the interface to the other bulk phase has received the most emphasis and is discussed in the next section.

2. INTERFACIAL PROFILES: THE MICROSCOPIC VIEW OF INTERFACIAL STRUCTURE

The origin of the interfacial tension is the microscopic arrangement of molecules in the transition region between bulk phases. Van der Waals related the interfacial tension to interfacial structure, specifically to the longitudinal number density profile $\rho(z)$ along the coordinate z normal to the interface. The theory was extended by Cahn and Hilliard (1958), and modern versions of van der Waals–type theories have been reviewed by Rowlinson and Widom (1982). Although it is recognized that the molecules are in constant thermal motion, these theories are concerned only with time-averaged profiles.

Buff *et al.* (1965) suggested an alternative viewpoint in which the interface is treated as a membrane whose shape varies as a result of thermal molecular motion. The shape is analyzed using capillary waves at the interface as the relevant collective coordinates. The longer-wavelength fluctuations of the interface cost very little energy and act to increase the effective width of the interface. This width is determined from an effective longitudinal density profile $\rho(z)$, calculated by averaging the structure over the transverse coordinates, x and y, at a particular height z. A hybrid approach, proposed by Weeks (1977), combines the intrinsic longitudinal density profile predicted from van der Waals theories and capillary-wave roughening of this intrinsic interface.

The characteristic length scales of the longitudinal interfacial profile can be estimated by dimensional analysis of the interfacial tension. The characteristic interfacial free energy may be estimated from the entropic loss of confining a molecule to the interface and is given by k_BT (k_B is Boltzmann's constant). For $\gamma \cong 40$ mN/m, the characteristic interfacial length scale ($\sim\sqrt{k_BT/\gamma}$) corresponding to the interfacial width is 0.3 nm; for small tensions characteristic of microemulsions such as $\gamma \cong 0.04$ mN/m, the width is 10 nm (Safran, 1994). For fluids near a critical point where the interfacial width is determined by a diverging correlation length (and $\gamma \rightarrow 0$), the width can be made as large as hundreds of nanometers. X-ray scattering has been most effective at studying interfacial profiles of simple liquids away from the critical point, and light scattering has been used near criticality (Langevin, 1992).

2.1 Density Profiles

In the classical van der Waals theory for the liquid–vapor interface, the inhomogeneity of the density at the interface is accounted for by adding to the free energy a term proportional to the square of the gradient of the density. Without this term the classical theory predicts a step-function profile for which the interface is an infinitely thin region representing an abrupt change from one bulk density to the other. However, the presence of the squared-gradient term implies an infinite free-energy cost for a step-function profile and, instead, predicts a diffuse interface with a gradual, continuous change in density from one bulk phase to the other as illustrated in Fig. 3.

Following the development in Rowlinson and Widom (1982), the number-density profile $\rho(z)$ along the coordinate z normal to the surface is given by

$$m\frac{d^2\rho(z)}{dz^2} = \mu[\rho(z),T] - \mu_0 = -\frac{dW(\rho)}{d\rho}, \tag{4}$$

where $\mu[\rho(z),T]$ is the chemical potential as a function of density and temperature and μ_0 is the uniform chemical potential in the bulk two-phase system. $W(\rho)$ is, therefore, an excess free-energy density due to the presence of the interface, specifically, the excess density of the grand potential Ω. The profile $\rho(z)$ is determined by solving Eq. (4) subject to the boundary conditions that $\rho = \rho_{l,v}$ at $z =$

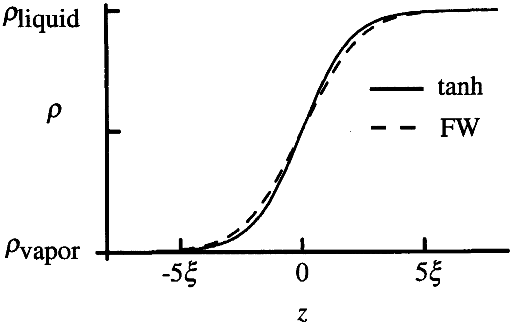

FIG. 3. The hyperbolic tangent (tanh) and Fisk–Widom (FW) intrinsic interfacial profiles.

$\pm\infty$. [The quantity m is given by the second moment of the attractive part of the intermolecular potential $u(r)$,

$$m = -\tfrac{1}{6}\int_{r>d} r^2 u(r)dr, \tag{5}$$

where $r > d$ indicates that the integral is taken only over the attractive part of the potential.] The surface tension is calculated from the density profile as

$$\gamma = \int_{-\infty}^{\infty} m\rho'(z)^2 dz = -2\int_{-\infty}^{\infty} W[\rho(z)]dz.$$

At a critical point (e.g., the liquid–vapor critical point) the two bulk phases become one (Hahne, 1983). As the critical point is approached, the densities of the two phases approach each other continuously. In a van der Waals mean-field theory, $W(\rho)$ near the critical point can be approximated as a quartic, which has two minima representing the two densities of the bulk phases. In this case, an explicit form for the profile (Fig. 3) can be given as

$$\rho(z) = \rho_c + \tfrac{1}{2}(\rho_l - \rho_v)\tanh[(z - z_0)/2\xi], \tag{6}$$

where ρ_c is the critical density, z_0 is arbitrary, and ξ is the Ornstein–Zernike correlation length of either bulk phase (ξ represents the exponential decay length of correlations between pairs of molecules). The interfacial width is of the same order as the bulk correlation length, which diverges as the critical point is approached in the manner $\xi \sim t^{-\nu}$, where $t = |T_c - T|/T_c$. The van der Waals theory is a mean-field theory with $\nu = \frac{1}{2}$ and is not valid very near the critical point. However, a slightly more accurate profile is given by substituting the nonclassical value for this exponent, $\nu \cong 0.63$. Fisk and Widom (1969) included realistic critical-point singularities in $W(\rho)$ and obtained

$$\rho(z) = \rho_c + \tfrac{1}{2}(\rho_l - \rho_v) \times \left[\frac{\sqrt{2}\tanh[(z - z_0)/2\xi]}{[3 - \tanh^2[(z - z_0)/2\xi]]^{1/2}}\right]. \tag{7}$$

This profile is similar to the classical profile given in Eq. (6), although slightly less steep (see Fig. 3). Experimental results to be discussed indicate a strong preference for the Fisk–Widom profile near criticality.

Van der Waals theories rely on a local thermodynamics, assuming that a local free-energy density can describe the inhomogeneous region of the interface that contains densities different from the stable bulk densities (at the chosen T and p). This local free-energy density is then a function of z, and it is assumed that it can be related to a bulk free energy evaluated at that intermediate density. The validity of these assumptions is not firmly established, and modern statistical mechanical theories of inhomogeneous liquid structure are written in terms of correlation functions that describe the correlations between pairs (and larger groups) of molecules. For example, the attractive part of the intermolecular potential, $u(r)$, in Eq. (5) is replaced by $-k_BTc(r)$, where $c(r)$ is the two-particle direct correlation function. In the modern theory, it is seen that Eq. (4) is an approximation to an integral equation of a functional of the entire density profile and is, therefore, nonlocal (Rowlinson and Widom, 1982). Integral equations have been used to determine numerical solutions for interfacial profiles. However, these solutions are not used often in the analysis of experimental data (though surface-tension values computed from integral equations have been compared, in some cases favorably, with measurements; see Rowlinson and Widom, 1982, for a discussion). In this article, we follow the experimental research literature in comparing measurements with the simpler analytic forms for the profiles.

2.2 Interfacial Fluctuations

In the original formulation of the capillary-wave theory of interfaces away from critical points, Buff *et al.* (1965) calculated the work W_{cw} necessary to create transverse oscillations in an interface of zero thickness. This consists of the work needed to deform the interface in a gravitational field and the work needed to create additional surface area of an interface with surface tension γ_{cw}. The interface is modeled as a taut membrane whose vibration modes (surface capillary waves) occur with a probability given by the Boltzmann distribution, $\exp(-W_{cw}/k_BT)$. In this theory the interface has a step-function *intrinsic* profile as given by van der Waals–

type theories discussed in the previous section. However, an effective profile can be calculated from the mean density $\rho(z)$ at any height z averaged over the values of the two bulk phases.

The capillary-wave theory postulates an effective Hamiltonian,

$$H_{\mathrm{cw}} = \gamma_{\mathrm{cw}} \int d^2s\left(\sqrt{1 + |\nabla\zeta|^2} - 1\right) + \tfrac{1}{2}\,\Delta\rho_m g \int d^2s\,\zeta^2, \tag{8}$$

where the first term accounts for the free-energy cost of the area change and the second term describes the gravitational-energy cost of a fluctuation. The interface lies, on average, in a two-dimensional plane whose coordinates are given by $\mathbf{s} \equiv (x,y)$, and the configuration of the interface is given by $z = \zeta(\mathbf{s})$, which represents the displacement of the interface from the x-y plane (Fig. 4). The capillary-wave theory can be extended to other dimensions, with interesting results reviewed by Gelfand and Fisher (1990).

Buff *et al.* identified the surface tension γ_{cw} used in their model with a bare surface tension of the interface without capillary waves. In an exact calculation for capillary waves in a one-dimensional interface of the two-dimensional Ising model, Abraham and Reed (1974, 1976) demonstrated that γ_{cw} is the actual surface tension, γ. Besides this result, there is not a firm theoretical foundation to guide the interpretation of γ_{cw} in the analysis of experimental data. In practice, most data analysis assumes $\gamma_{\mathrm{cw}} = \gamma$.

If the fluctuations are of long wavelength or small amplitude, the square root in Eq. (8) can be expanded, resulting in a Gaussian form for the effective Hamiltonian,

$$H_{\mathrm{cw}} = \tfrac{1}{2}\,\gamma_{\mathrm{cw}} \int d^2s\left[|\nabla\zeta|^2 + \left(\frac{\zeta}{\xi_{\|,\mathrm{cw}}}\right)^2\right], \tag{9}$$

where the capillary-wave interfacial correlation length $\xi_{\|,\mathrm{cw}}$ is given by $\xi^2_{\|,\mathrm{cw}} = \gamma_{\mathrm{cw}}/\Delta\rho_m g$ and determines the exponential decay of the interfacial correlations given by the height–height correlation function $\langle\zeta(\mathbf{s})\zeta(\mathbf{s}')\rangle$ (Gelfand and Fisher, 1990). The actual correlation length, $\xi_{\|}$, is given by $\xi_{\|}^2 = \gamma/\Delta\rho_m g = a^2/2$, where a is the capillary length introduced earlier and is of macroscopic dimensions.

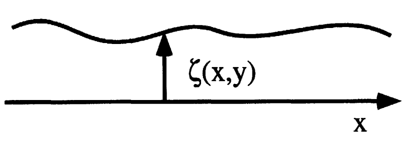

FIG. 4. Interfacial configuration along *x*-axis.

Equation (9) can be analyzed by expressing the interfacial configuration $\zeta(\mathbf{s})$ in terms of decoupled harmonic interfacial waves (capillary waves). The average over the canonical ensemble of all accessible interfacial waves, $\langle\zeta^2\rangle$, is given (in three dimensions) as

$$\langle\zeta^2\rangle = \frac{k_{\mathrm{B}}T}{2\pi\gamma_{\mathrm{cw}}} \int_{q_{\min}}^{q_{\max}} \frac{q\,dq}{q^2 + \xi^{-2}_{\|,\mathrm{cw}}}, \tag{10}$$

where q is the wave number of the surface capillary wave. The cutoff $q_{\max}$ represents the shortest-wavelength capillary mode on the interface. It is reasonable to expect that the shortest wavelength should be no smaller than the molecular size, thereby setting an upper limit for $q_{\max}$. This short-wavelength behavior of the capillary-wave model is under debate, and currently, there is not a consensus on how to choose $q_{\max}$ from either theoretical or experimental considerations. In the Buff *et al.* model, $q_{\max}$ is chosen as inversely proportional to the interfacial width, $q_{\max} = \pi/\langle\zeta^2\rangle^{1/2}$. The cutoff $q_{\min}$, corresponding to the largest-wavelength capillary mode, is determined by the system size as $q_{\min} = \pi/D$ (e.g., for a square interface of area D^2). Individual experimental techniques may not be sensitive to wavelengths as large as the system size, thereby increasing the effective $q_{\min}$. By integrating Eq. (10) we have

$$\langle\zeta^2\rangle = \frac{k_{\mathrm{B}}T}{4\pi\gamma_{\mathrm{cw}}} \ln\left(\frac{q^2_{\max} + \xi^{-2}_{\|,\mathrm{cw}}}{q^2_{\min} + \xi^{-2}_{\|,\mathrm{cw}}}\right). \tag{11}$$

In the thermodynamic limit ($D = \infty$) the interfacial width $\langle\zeta^2\rangle$ diverges as $g \to 0$. Similarly for fixed $g = 0$, $\langle\zeta^2\rangle$ diverges as $D \to \infty$. This delocalization of the interface is not consistent with the van der Waals theories.

The capillary theory of Buff *et al.* with a step-function intrinsic profile leads to an error-function profile

$$\rho(z) = \tfrac{1}{2}(\rho_l + \rho_v) + \tfrac{1}{2}(\rho_l - \rho_v)\,\mathrm{erf}(\sqrt{\pi}z/L) \text{ with}$$
$$\mathrm{erf}(z) = \frac{2}{\sqrt{\pi}} \int_0^z e^{-t^2}dt, \tag{12}$$

where $\sqrt{24}L = \xi$ [to be compared with Eq. (7)]. The central region of this profile is almost identical to the Fisk–Widom profile in Eq. (7) and only differs slightly in the wings (for $|z| \cong 4\xi$).

An important extension of the capillary-wave theory was made by Weeks (1977) in which a smooth intrinsic profile is further roughened by capillary waves. Here, $q_{\max} \cong \pi/\xi$, where ξ is the bulk correlation length that sets the width of the intrinsic profile. This hybrid model includes an intrinsic profile for in-plane length scales less than ξ and capillary waves on longer length scales. The profile $\rho(z)$ is a convolution of the error-function capillary-wave profile and the intrinsic profile. The surface tension γ_{cw} is taken to be the actual surface tension, γ.

Meunier (1987) introduced coupling between surface waves of different q that results in a q-dependent surface tension $\gamma(q)$. The shorter-wavelength capillary waves renormalize the surface tension associated with longer-wavelength waves, as first suggested by Stillinger (1967). Meunier's analysis leads to the expression for the interfacial width

$$\langle \zeta^2 \rangle \propto k_{\mathrm{B}} T \int_{q_{\min}}^{q_{\max}} \frac{q\,dq}{\gamma_{\mathrm{cw}}(q) q^2 + \Delta\rho_m g}, \tag{13}$$

where $\gamma_{\mathrm{cw}}(q) \approx \gamma + \tilde{\nu} q^2 + \ldots$. In this theory the intrinsic interface is a step function, and the coupling between the capillary waves introduces a natural cutoff, $q_{\max}$. Sengers and van Leeuwen (1989) built upon this coupled-mode analysis to introduce a hybrid model accounting for both an intrinsic interface and capillary waves.

The q-dependent surface tension has been used recently to analyze optical measurements of interfaces. However, a direct experimental verification of this q dependence is not available. On a related topic, the analysis of measurements of surfactant-covered surfaces utilizes a q^4 term in the denominator of Eq. (13) to account for the elasticity of the interface. In this case there will be an additional energy cost associated with bending under area-conserving conditions, and the prefactor of the q^4 term is then proportional to an elastic bending modulus (Safran, 1994).

Napiórkowski and Dietrich (1993) used microscopic density-functional theory for inhomogeneous media to derive a nonlocal effective Hamiltonian for a fluctuating liquid–vapor interface with a step-function intrinsic profile. The Hamiltonian is expressed in terms of $\tilde{w}(|\mathbf{r}' - \mathbf{r}|)$, a particle–particle interaction potential of, e.g., long-range van der Waals forces, and is written as

$$\begin{aligned} H([\zeta]) &= \int_{\mathbf{s}} d^2 s\, h_0(\mathbf{s},[\zeta]) \\ &\quad + (m/2)(\Delta\rho) g \int d^2 s\, \zeta^2, \text{ with} \\ h_0(\mathbf{s},[\zeta]) &= -\tfrac{1}{2}(\Delta\rho)^2 \int_{\mathbf{s}} d^2 s \int_0^{\infty} dz \int_0^{\zeta(\mathbf{s}')-\zeta(\mathbf{s})} \\ &\quad \times dz'\, \tilde{w}(|\mathbf{r}' - \mathbf{r}|), \end{aligned} \tag{14}$$

where m is the mass of the particles. The second term in $H([\zeta])$ corresponds to the gravitational term in Eq. (8). The first term in Eq. (8) can be derived from the first term of $H([\zeta])$ by expanding $\zeta(x',y') - \zeta(x,y)$ in powers of $x' - x$ and $y' - y$ and keeping only the linear terms; that is, the Hamiltonians are equivalent in the limit of slowly varying interfaces. This nonlocal Hamiltonian behaves very differently from the standard local Hamiltonian H_{cw} [Eq. (8)] in the region of large q. Similar to the theory of Meunier, this Hamiltonian predicts a q-dependent surface tension. Napiórkowski and Dietrich have shown that this Hamiltonian implies that the interpretation of experimental measurements is strongly dependent on the wave-vector cutoff, $q_{\max}$.

3. ADSORPTION AND WETTING PHENOMENA

In a single-phase liquid mixture of two or more components the component whose surface tension as a pure system is lowest will be adsorbed preferentially at the liquid–vapor interface. Similarly, addition of a low-surface-tension impurity to a liquid will lower the surface tension of the mixture because of adsorption of the impurity at the surface. These, and related, adsorption phenomena are described by the Gibbs adsorption equation, given by

$$d\gamma + \eta_s dT + \Sigma \Gamma_i d\mu_i = 0, \tag{15}$$

which relates the change in the surface tension to changes in the temperature T and the chemical potentials of the i components in the bulk. Here η_s is the excess or surface entropy density, $\eta_s = S^s/A$. The adsorption can be defined in terms of the interfacial profile $\rho(z)$:

$$\Gamma_i = \int_{-\infty}^{\infty} [\rho_i(z) - \rho_{\alpha,\beta}]dz, \tag{16}$$

where $\rho_{\alpha,\beta}$ is the value of ρ on the α or β side of an arbitrarily chosen dividing surface. As an example, consider a two-component system at constant temperature with a dividing surface chosen so that $\Gamma_1 = 0$. Equation (15) is then rewritten as $\Gamma_2 = -(\partial\gamma/\partial\mu_2)_T$. In the case of water–ethanol mixtures (where water is component 1 and ethanol is component 2), measurements of the surface tension as a function of ethanol content yield $(\partial\gamma/\partial\mu_2)_T < 0$. Therefore $\Gamma_2 > 0$, indicating a surface excess of ethanol (Adamson, 1990). Using Eqs. (15) and (16), measured changes in surface tension can, in principle, be related to measurements of the microscopic density profiles.

Fisher and de Gennes (1978) proposed that adsorption at an interface can be significantly enhanced near a critical point. For example, consider a single-phase binary liquid mixture consisting of components A and B in a sample cell whose walls preferentially attract component A (this attraction is typically characterized in terms of a surface field h_1). When the mixture is in a single phase far from the critical point (where the single phase separates into two phases), a thin layer of component A (typically on the order of a monolayer) will be found adsorbed to the walls. As the critical point is approached, the pair correlation length between A molecules in the bulk diverges, and Fisher and de Gennes predict that the adsorption of A will be enhanced at the walls. Heuristically, the walls provide a boundary condition that pins bulk critical fluctuations of component A to the wall. This critical adsorption profile should scale as

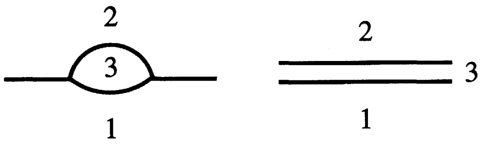
$$\rho(z) - \rho_{\text{bulk}} \cong \rho_0 t^{\beta} f(z/\xi, h_1/t^{\Delta_1}), \tag{17}$$

where $\Delta_1 > 0$ implies that the scaled surface field h_1/t^{Δ_1} diverges as $t \to 0$ ($t = |T_c - T|/T_c$), strongly enhancing the attraction of the preferentially adsorbed component. In this strong-field limit, the scaling function $f_{\text{sat}}(z/\xi) \equiv f(z/\xi,\infty)$. At criticality, $t = 0$, the scaling function $f(z/\xi) \approx f_0(z/\xi)^{-\beta/\nu}$ as $z/\xi \to 0$, giving an algebraically decaying interfacial profile. Away from criticality, the decay of the interfacial profile is exponential and is determined by the bulk correlation length with $f(z/\xi) \approx f_\infty e^{-z/\xi}$ as $z/\xi \to \infty$. This leads to the expectation that the adsorption diverges as $t^{\beta-\nu}$ when $t \to 0$ (where $\beta = 0.325$ and $\nu = 0.63$). Several groups made the earliest measurements on organic binary liquids (Beaglehole, 1980; Beysens and Leibler, 1982; Franck and Schnatterly, 1982), and others are reviewed by Liu and Fisher (1989). Measurements by Franck and co-workers have explored the role of the surface field h_1, including measurements of the strong- and weak-field limits (Schlossman *et al.*, 1985; Desai *et al.*, 1995). Although there are numerous measurements of critical adsorption, the full scaling of the profile has not been completely confirmed (Smith and Law, 1995).

A wetting transition is illustrated in Fig. 5 where a droplet of phase 3 situated at the interface between phases 1 and 2 [Fig. 5(a)] spreads to form a continuous film separating phases 1 and 2 [Fig. 5(b)]. In the latter situation, phase 3 is said to have wetted the interface, and Antonow's rule gives the relationship between the interfacial tensions:

$$\gamma_{12} = \gamma_{13} + \gamma_{32}. \tag{18}$$

If phase 3 does not wet the 1–2 interface, then $\gamma_{12} < \gamma_{13} + \gamma_{32}$ [Fig. 5(a)]. Cahn (1977) introduced the idea of a wetting transition expected to occur ubiquitously in systems near their critical point. Since then numerous theoretical and experimental studies of wetting transitions have been published. Here we mention a few highlights of these



(a) (b)

FIG. 5. (a) Incomplete wetting. (b) Complete wetting of phase 3 at the 1–2 interface.

studies and refer to them later in the discussion of experimental data (for a review, refer to Sullivan and da Gama, 1986, and Dietrich, 1988).

Some of the phenomena associated with wetting transitions are summarized in Fig. 6, which illustrates the $(\Delta\mu,T)$ plane in the neighborhood of the liquid–vapor critical point for a one-component system, where $\Delta\mu = \mu - \mu_{\text{coexistence}}$ (the chemical-potential difference from liquid–vapor coexistence) (Pandit *et al.*, 1982). In this circumstance, phase 1 in Fig. 5(a) is an inert phase such as a container wall, and wetting occurs when a macroscopic layer of liquid spreads at the wall in the presence of bulk vapor. Along the horizontal axis, $\Delta\mu = 0$, for $T < T_c$ bulk liquid and vapor coexist. As $T \rightarrow T_w$, the wetting transition temperature, from below (along the $\Delta\mu = 0$ line), a first-order transition at the vapor-wall interface occurs at which the adsorption of the liquid phase at the wall diverges to give a macroscopic liquid layer (complete wetting). With further increase of the temperature (for $\Delta\mu = 0$), the system reaches the bulk critical point at $T = T_c$. Similarly, following path (a) the adsorption increases by a finite amount at the prewetting line. The prewetting transition that occurs at the prewetting line consists of a finite change from a thin layer adsorbed at the wall to a thick adsorbed layer. Along the prewetting line, there is predicted to be coexistence of thin and thick layers on the surface. The magnitude of this finite change in thickness increases for temperature scans at progressively smaller $\Delta\mu$ and diverges as $\Delta\mu \rightarrow 0$, at the point where the prewetting line joins the coexistence line at T_w. The magnitude of the change in thickness vanishes at C_{pre}, the prewetting critical point.

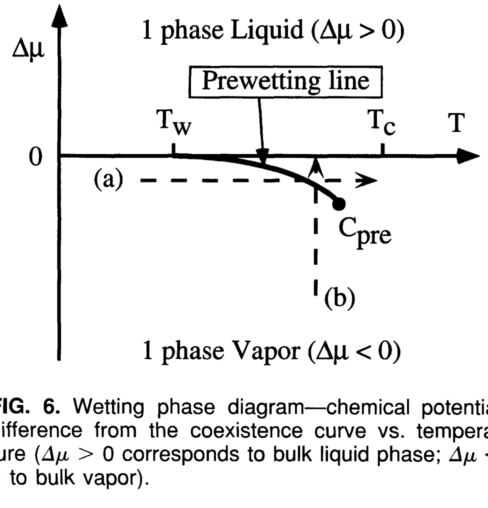


FIG. 6. Wetting phase diagram—chemical potential difference from the coexistence curve vs. temperature ($\Delta\mu > 0$ corresponds to bulk liquid phase; $\Delta\mu < 0$ to bulk vapor).

Alternatively, on fixing the temperature at $T < T_w$ and scanning $\Delta\mu$ from $\Delta\mu < 0$ to $\Delta\mu = 0$, the adsorption is expected to increase only slightly to a finite microscopic value at the coexistence curve (incomplete wetting). For $T > T_w$ along path (b) in Fig. 6, the same variation of $\Delta\mu$ results first in a finite change in adsorbed layer thickness as the prewetting line is crossed and then in a diverging layer thickness as the coexistence curve is approached (complete wetting). For many experimental systems first-order wetting transitions are observed, yet the prewetting line is not. It is believed that this occurs because the prewetting line is too close to the coexistence line to be observable. However, for several systems that are very weakly bound to the substrate, the prewetting transition has been unambiguously observed. This is the case for ^{4}He on the alkali-metal surfaces Rb and Cs (and also observed for H_2 and D_2 on Rb and, possibly, for Ne on Cs) (Taborek and Rutledge, 1994; Cole, 1995).

This phenomenology of wetting and prewetting transitions was originally developed using theories incorporating short-range interactions only. These surface phenomena are very sensitive to the form and magnitude of the interactions, which include both the interparticle potentials and wall or surface potentials. For the appropriate choice of potentials, the first-order wetting transition is expected to become second order. In this case the prewetting line does not appear. The adsorption and the interfacial profiles are also very sensitive to the potentials. For example, long-range forces such as van der Waals forces, electrostatic forces, and gravity can have a significant effect on the surface adsorption.

Similar phenomenology also occurs in the study of multilayer adsorption of, for example, low-temperature gases on solid graphite or, as discussed more extensively below, liquid-crystal layering at the free surface. In these cases, complete wetting corresponds to a buildup of a macroscopic number of adsorbed layers. Incomplete wetting corresponds to the surface saturating at a finite number of adsorbed layers. Closer approach to the bulk coexistence line then results in the growth of bulk islands that do not spread over the surface to form complete layers.

Understanding wetting phenomena is also of relevance for the study of first-order bulk transitions. Nucleation of a new phase may be more favorable at the walls of the container, especially if the new phase completely wets the walls. Wall effects on both spinodal decomposition and nucleation play a particularly important role for fluids confined in one or more directions such as in thin cells or in porous materials.

Because of limited space, this article does not review the vast number of experiments in this field. However, a few experimental results on wetting in liquid crystal systems are discussed for which measurements of the microscopic structure are available.

4. INTERFACIAL-PROFILE MEASUREMENTS

X-ray and light scattering have been particularly useful probes for determining interfacial profiles at liquid interfaces. X-ray reflectivity measurements probe the gradient of the longitudinal electron density profile, $d\rho_e/dz$. X-ray surface diffuse scattering directly probes the interfacial fluctuations. Similarly light-reflectivity measurements probe the width of the profile, but on longer length scales than for x-ray reflectivity, making it a useful technique closer to the critical point where the profile width is expected to diverge.

4.1 X-Ray Measurements of Interfaces far from Criticality

Specularly reflected x rays have a wave-vector transfer normal to the interface; therefore, they probe the longitudinal profile (specifically, the electron-density profile) averaged over the transverse directions. The kinematics for this reflection is shown in Fig. 7 where $\theta_{\text{in}} = \theta_{\text{scat}}$ for specular reflection and the wave-vector transfer $\mathbf{Q} = \mathbf{k}_{\text{scat}} - \mathbf{k}_{\text{in}}$ (the difference between the scattered and incident wave vectors) is given by $Q_z = (4\pi/\lambda)\sin\theta$ and $Q_x = Q_y = 0$ (λ is the x-ray wavelength, and the reflection angle $\theta \equiv \theta_{\text{in}}$).

With neglect of multiple scattering, the first Born approximation can be used to calculate the specularly reflected x-ray intensity $R(Q_z)$ (Pershan, 1990):

$$\frac{R(Q_z)}{R_F(Q_z)} \cong \left| \frac{1}{\rho_{e,\text{bulk}}} \int dz \, \frac{d\langle\rho_e(z)\rangle}{dz} \exp(iQ_z z) \right|, \qquad (19)$$

where $d\langle\rho_e(z)\rangle/dz$ is the electron-density gradient averaged over the x-y plane, $\rho_{e,\text{bulk}}$ is the electron density far below the surface, and $R_F(Q_z)$ is the Fresnel reflectivity for a smooth step-function interface. This approximation is accurate for reflection angles $\theta \gtrsim 4\theta_c$, where the critical angle for total x-ray reflection, $\theta_c \cong \sqrt{\rho_e r_e \lambda^2/\pi}$ ($r_e = e^2/mc^2 \cong 2.818$ fm), is small (for example, $\theta_{c,\text{water}} \cong 0.15°$ for $\lambda = 0.154$ nm). Note that θ is measured from the surface plane, in contrast to optical measurements for which it is conventional to measure θ from the surface normal. X-ray scattering from liquid surfaces is reviewed by Schlossman and Pershan (1992).

If the error-function profile in Eq. (12) is used in Eq. (19), the x-ray reflectivity is written as

$$R(Q_z)/R_F(Q_z) = \exp(-Q_z^2\sigma^2), \qquad (20)$$

where the constant σ is a measure of the interfacial width and is related to the L in Eq. (12) by $\sigma = L/\sqrt{2\pi}$. In the spirit of a hybrid model of the interface that describes an intrinsic profile further roughened by capillary waves, the interfacial width σ can be represented as a combination of an intrinsic width σ_0 and the capillary-wave contribution [Eq. (10)] (Braslau *et al.*, 1985, 1988; Schwartz *et al.*, 1990):

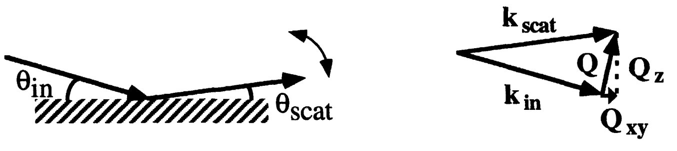

FIG. 7. Kinematics for surface scattering in the plane of incidence.

$$\sigma^2 = \sigma_0^2 + \frac{k_B T}{2\pi\gamma}\int_{q_{\min}}^{q_{\max}} \frac{q\,dq}{q^2 + \xi_\parallel^{-2}}, \qquad (21)$$

where $q_{\min}$ is determined by the instrumental resolution that sets the largest in-plane wavelength that the measurement probes. Consequently, once the instrumental resolution and the incident angle have been set, σ^2 is specified in terms of only two adjustable parameters: the intrinsic width of the electron-density profile σ_0 and the limit $q_{\max}$. Although the integration in Eq. (21) actually results in a logarithmic dependence of σ^2 on Q_z, the variation is slow, and data are often well represented by a value of σ^2 that is independent of Q_z but logarithmically dependent on the instrumental resolution.

X-ray specular reflectivity data from the surface of H_2O far from a critical point ($T \cong$ 20 °C), as shown in Fig. 8(a), are typical of the reflectivity from pure liquid surfaces (Schwartz *et al.*, 1990). These data were taken from the surface of H_2O in a vapor- and temperature-controlled Langmuir trough in which the surface tension was monitored *in situ* to be 72.5 ± 0.4 mN/m. There is a small region for $\theta < \theta_c$ where the reflectivity is essentially 100% (corresponding to total reflection), followed by a rapid fall. As shown in Fig. (8b) where the same data are normalized to $R_F(Q_z)$ and plotted as $R(Q_z)/R_F(Q_z)$ versus Q_z^2 on a semilogarithmic scale, the data are well represented by the form in Eq. (20) where $\sigma^2 = (0.270 \pm 0.003\ \text{nm})^2$. The two parameters, σ_0 and $q_{\max}$, cannot be distinguished by this set of measurements; therefore, the lines displayed in Fig. 8 were determined by fits to $q_{\max}$ only (with the intrinsic width, σ_0, set to zero). The lines in Figs. 8(a) and 8(b) display this fit, with $q_{\max} = \pi/(0.14 \pm 0.01\ \text{nm})$. By changing the slit size that determines the angular acceptance of the detector, the instrumental resolution can be varied, thereby varying $q_{\min}$. This allows the dependence of the integral in Eq. (21) on the limit $q_{\min}$ to be tested. Figure (8c) displays the comparison of the measured values of σ^2, as obtained from the best fits like that represented by the solid line in Fig. (8b), and those calculated for $Q_z = 4\ \text{nm}^{-1}$. This shows good agreement with the theoretical form of Eq. (21). However, these x-ray measurements cannot distinguish between the use of one particular value of $q_{\max}$ for an interface that is locally sharp and alternative hypotheses about the nature of the intrinsic interfacial structure.

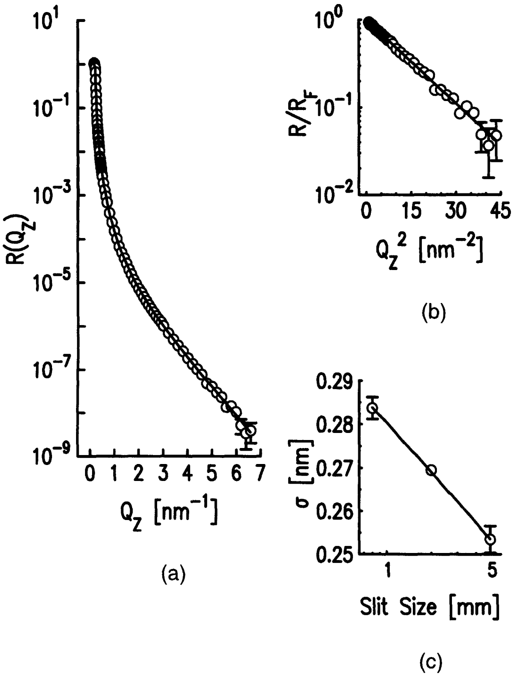

FIG. 8. Measured x-ray reflectivity from a water–vapor interface (see text for explanation).

In a related x-ray reflectivity measurement by Ocko *et al.* (1994) of the liquid–vapor interface of two long-chain alkanes, $C_{20}H_{42}$ and $C_{36}H_{74}$, the temperature was varied from 40 °C to 140 °C to distinguish the effects of the two terms in Eq. (21). The measurements are well described by the hybrid model represented by Eq. (21). The intrinsic width, σ_0, was determined to be $\sigma_0 = 0.11$ nm with a $q_{\max} = \pi/(0.71\ \text{nm})$ for $C_{20}H_{42}$ and $q_{\max} = \pi/(1.16\ \text{nm})$ for $C_{36}H_{74}$. These measurements could not be explained by the Buff *et al.* (1965) theory for which $\sigma_0 = 0$, or by the mode-coupling theory of Meunier (1987). Earlier measurements by Braslau *et al.* (1988) on the surfaces of CCl_4 and CH_3OH fixed $\pi/q_{\max}$ to be the molecular radius and fitted the reflectivity to σ_o. For CCl_4, σ_0 varied from 0.25 to 0.39 nm as the instrumental resolution was varied. These values are close to the molecular radius of 0.388 nm, but the variation with instrumental resolution is unexplained. For the surface of methanol the intrinsic profile was very small, $\sigma_0 = 0.07 \pm$

0.04 nm, much smaller than the molecular radius of 0.252 nm.

To summarize these reflectivity measurements, some indicate that both the intrinsic profile and the capillary-wave profile as given in Eq. (21) are necessary to fit the measurements. However, the physical significance of the numerical results for the fitting parameters, σ_0 and $q_{\max}$, is unclear and is not directly related to the predictions of hybrid capillary-wave models such as that given by Weeks for which both σ_0 and $\pi/q_{\max}$ should be of the order of the bulk correlation length.

Both neutron and x-ray specular reflectivity probe the scattering density averaged over the interfacial plane. For this reason, specular reflectivity measurements cannot distinguish between a rough interface and one with a graded scattering density profile of a certain width, but without roughness or fluctuations. In the model of thermally excited capillary waves, the reflectivity differs from the Fresnel reflectivity because the surface waves scatter the radiation out of the specular condition (the Fresnel reflectivity is expected for an ideal flat and sharp interface). This surface diffuse scattering directly measures the presence of fluctuations of the surface (recent reviews are given by Schlossman and Pershan, 1992, and Dietrich and Haase, 1995).

Figure 9 shows the measured intensity at a fixed angle of incidence (shown for two different incident angles) as the scattering angle θ_{scat} is varied (see Fig. 7). When the incident angle θ_{in} is equal to the scattering angle θ_{scat} there is a peak corresponding to the specular scattering. For other scattering angles, $\theta_{\text{scat}} \neq \theta_{\text{in}}$, the wave-vector transfer $\mathbf{Q} = \mathbf{k}_{\text{scat}} - \mathbf{k}_{\text{in}}$ (see Fig. 7) has a component in the plane of the interface, Q_{xy}, that probes the in-plane structure. In Fig. 9 a small peak appears when $\theta_{\text{scat}} = \theta_c$ (the angle for total reflection) at which the surface diffuse scattering is enhanced above the bulk diffuse scattering. On account of the multiple scattering that occurs near total reflection, the distorted-wave Born approximation is needed to calculate the scattering intensity near the critical angle θ_c as

$$I(\mathbf{Q}) \propto |T(\theta_{\text{in}})|^2 |S(\mathbf{Q})|^2 |T(\theta_{\text{scat}})|^2, \qquad (22)$$

where $S(\mathbf{Q})$ is the scattering structure factor, and $T(\theta)$ is the Fresnel transmission coefficient (Becker *et al.*, 1983; Deitrich and Wagner, 1984, 1985; Dosch, 1987). The function $|T(\theta)|^2$ varies from 0 to 4 as θ increases from 0 to θ_c and then falls to unity for $\theta \gg \theta_c$. The angular dependence of the two factors $T(\theta_{\text{in}})$ and $T(\theta_{\text{scat}})$ enables the surface scattering to be distinguished from other diffuse-scattering processes by giving rise to the peak at $\theta_{\text{scat}} = \theta_c$ for a rough interface. Note that an ideally smooth interface would not exhibit this surface enhancement peak.

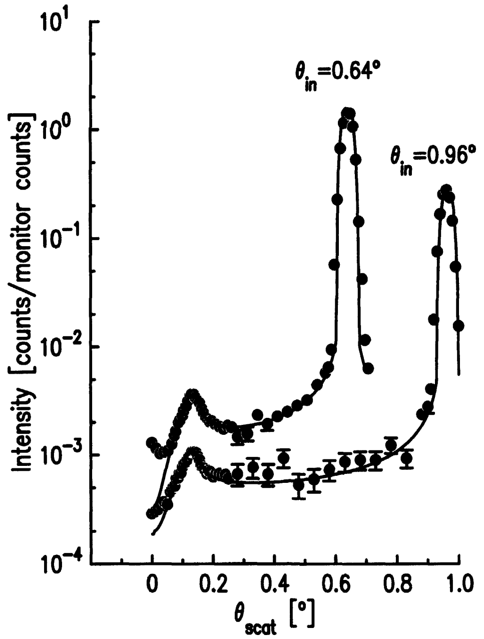

FIG. 9. Scattered x-ray intensity, in the plane of incidence, as a function of scattered angle for two fixed incident angles.

The solid lines in Fig. 9 represent the prediction for the scattered intensity I_D, written as

$$I_D \cong I_0 \frac{(r_e\rho_e)^2}{\theta_{\text{in}}\Delta\theta_{\text{in}}} \frac{k_B T}{\gamma} \int_{\theta_{\text{in}}-\Delta\theta_{\text{in}}/2}^{\theta_{\text{in}}+\Delta\theta_{\text{in}}/2} d\theta_{\text{in}} \int_{-\Delta\phi/2}^{\Delta\phi/2} d\phi \times \int_{\theta_{\text{scat}}-\Delta\theta_{\text{scat}}/2}^{\theta_{\text{scat}}+\Delta\theta_{\text{scat}}/2} d\theta_{\text{scat}} \frac{|T(\theta_{\text{in}})|^2 |T(\theta_{\text{scat}})|^2}{q^2 + \xi_{\|,\text{cw}}^{-2}}, \qquad (23)$$

where the integrations are over the instrumental resolution $\Delta\theta_{\text{in}}$, $\Delta\theta_{\text{scat}}$, and $\Delta\phi$ (ϕ is the azimuthal in-plane angle of the detector), and I_0 is the incident intensity. This expression for the scattered diffuse intensity assumes that the intrinsic profile is a step function, and is also an approximation for weak height–height correlations. More general expressions are discussed by Sinha *et al.* (1988) and Dietrich and Haase (1995). The only adjustable parameter for the fit in Fig. 9 is a small constant background, of the order of 10% of the peak at $\theta_{\text{scat}} = \theta_c$. The high quality of the fit indicates that the capillary-wave model is a good representation of the interfacial fluctuations with wavelengths from 40 to 8000 nm (Schwartz *et al.*, 1990). Combining these measurements with optical light scattering allows the capillary-wave theory to be tested over capillary wavelengths from 40 nm to ~1 mm (Loudon, 1984).

Sinha and co-workers have pointed out that the height–height correlation function $\langle \zeta(\mathbf{s})\zeta(\mathbf{s}')\rangle$ for capillary waves should exhibit a power-law decay as seen generally for displacement–displacement correlations in two-dimensional systems (Sinha *et al.*, 1988; Sanyal *et al.*, 1991). In general, power-law singularities of the form $Q^{\eta-2}$ appear in the structure factor $S(Q)$ of two-dimensional systems. For the experiments of Sanyal *et al.* on the surface of ethanol, this singularity appears in the scattered intensity as $I_D(Q_{xy}) \sim Q_y^{\eta-1}$ because of integration over the Q_x direction due to a large angular acceptance normal to the scattering plane (Sanyal *et al.*, 1991). In this case the exponent η is given by $\eta = (k_BT/2\pi\gamma)Q_z^2$. Their data are consistent with capillary-wave theory with a step-function intrinsic profile and show clearly the predicted power-law region over slightly more than a decade in Q_y. Their analysis yields an interfacial width of 0.69 ± 0.02 nm. Zhao *et al.* (1992) used similar techniques to study the liquid–vapor interface of toluene and of semidilute solutions of polybromostyrene and toluene. For sufficiently concentrated polymer solutions it is expected that the liquid-surface modes will be altered by the viscoelasticity of the polymer solution. However, in this case, even though the solutions were well into the entangled regime, they exhibited behavior in agreement with the standard capillary-wave theory (with a step-function intrinsic interface), as did the pure toluene surface.

4.2 Optical Measurements of Interfaces near Criticality

Optical reflectivity, ellipsometry, and dynamic light scattering have been used to study liquid interfaces. Optical reflectivity is sensitive to structures on length scales of ~10 nm or longer and has been used primarily to study near-critical interfaces where the interfacial thicknesses are on the order of 100 nm or more. Ellipsometry is sensitive to thinner layers and, as shown by Meunier, is more sensitive to the effect of smaller-wavelength capillary waves than is reflectivity. Dynamic light scattering is a useful probe of structure and dynamics on length scales for which $Q\lambda < 1$ (~10 to ~100 μm). The information on interfacial dynamics measured by dynamic light scattering from liquid interfaces is outside the scope of this article and has been reviewed recently by Langevin (1992).

Early optical reflectivity measurements near the critical temperature were made by Webb and co-workers on the liquid–vapor interface of SF_6 and the liquid–liquid interface of cyclohexane and methanol mixtures (Huang and Webb, 1969; Wu and Webb, 1973). These measurements were analyzed to determine both the functional form of the interfacial profile and the temperature scaling of the profile width. Since the profile width is expected to scale as the bulk correlation length, $\xi \sim t^{-\nu}$, where $t = |T_c - T|/T_c$, these measurements provided one of the early experimental determinations of the critical exponent ν. Similar to x-ray reflection, the optical reflectivity is interpreted using a Born approximation resulting in an equation very similar to Eq. (19) where the gradient of the index of refraction replaces the electron-density gradient, $d\rho(z)/dz \Rightarrow dn(z)/dz$. These measurements were not consistent with the van der Waals hyperbolic tangent profile given in Eq. (6), but were accurately described by the Fisk–Widom profile in Eq. (7) and the error-function profile in Eq. (12), with a slight preference for the error-function profile predicted for capillary waves on a step-function intrinsic profile. Values of ν determined by the fits by the error-function profile (e.g., $\nu = 0.62 \pm 0.01$) are also closer to the currently accepted value of $\nu = 0.63$ than those determined by the fits by the Fisk–Widom profile (e.g., $\nu = 0.663 \pm 0.02$) (Wu and Webb, 1973).

These early reflectivity measurements have been reanalyzed by several authors using hybrid models for the interface that combine the effects of capillary waves and the intrinsic profile as well as taking advantage of more recent measurements of bulk parameters, such as ν, that affect the analysis of the interfacial profile. Beysens and Robert (1987) determined that the reflectivity measurements on SF_6 and methanol-cyclohexane solutions could not be explained using only an intrinsic profile, but it was not clear whether a hybrid theory was required or if capillary-wave theory alone was adequate (with a step-function intrinsic profile) (Beysens and Robert, 1987). Sengers *et al.* (1991) used a hybrid theory that incorporated a q-dependent surface tension and determined that the predicted temperature dependence (near the critical point) of the profile was consistent with the measurements on the binary fluid, but not with those on SF_6. In addition, using their prediction for $q_{\max}$, they determined that the theory overestimates the measured reflectivity by 15–20% for the binary fluid.

Ellipsometry has been used to study the liquid–vapor interface and the liquid–liquid interface of many fluids, including a few measurements near the critical point (Beaglehole, 1986, 1987; Croxton, 1986; Schmidt, 1988, 1991; Miles and Schmidt, 1990; Schmidt and Moldover, 1993). Here, we discuss some recent measurements by Schmidt and co-workers on single-component and binary liquid mixtures near criticality.

The ellipticity of an interface is given by the ratio of the complex reflectivity coefficients, r_p/r_s, given by

$$\rho(\theta) = r_p(\theta)/r_s(\theta) = |r_p(\theta)/r_s(\theta)|e^{i\Delta(\theta)}, \qquad (24)$$

where the reflectivity coefficients for p- or s-polarized light relate the reflected electric field E_r to the incident electric field E_i as $E_i^{p,s} = r_{p,s}E_i^{p,s}$; θ is the angle of incidence (θ is measured from the interfacial normal), and Δ is a phase shift. The ellipticity is often measured at the Brewster angle θ_B, where $\Delta = \pi/2$. This results in a measurement of $\bar{\rho} = \mathrm{Im}[\rho(\theta)]_{\theta=\theta_B}$. In this notation, the intensity of the p- or s-polarized specular reflectivity is given by $R_{p,s}(\theta) = |r_{p,s}(\theta)|^2$.

Schmidt and co-workers interpret their measurements of $\bar{\rho}$ in terms of a combination of ellipticities due to the Fisk–Widom intrinsic interface and to a sharp interface roughened by capillary waves, $\bar{\rho} = \bar{\rho}_{FW} + \bar{\rho}_{cw}$. The ellipticity is expected to scale with temperature as

$$\bar{\rho} \approx \frac{\sqrt{2}\pi}{\lambda} \Delta n_0 \xi_0^- t^{\beta-\nu}(\chi_{FW} + \chi_{cw}), \qquad (25)$$

where Δn_0 is an amplitude in the expression for the index of refraction near the critical point given by $n_\pm = n_c \pm \Delta n_0 t^\beta/2$, ξ_0^- is given by the expression for the bulk correlation length near the critical point in the two-phase region by $\xi^- = \xi_0^- t^{-\nu}$, and χ_{FW} and χ_{cw} are constants determined, respectively, by the choice of intrinsic profile and by the choice of capillary-wave theory. Schmidt and co-workers chose to determine χ_{cw} from either the theory of Meunier ($\chi_{cw} \cong 1.43$) or that of Sengers and van Leeuwen ($\chi_{cw} \cong 1.39$) and used $\chi_{FW} \cong 2.28$ from the Fisk–Widom profile (Schmidt and Moldover, 1993). Equation (25) indicates that the quantity $\bar{\rho}\lambda/\Delta n_0 \xi^- \sqrt{2}\pi$ is universal and should yield a universal constant, $\chi = \chi_{FW} + \chi_{cw}$. This is expected to be true for both the liquid–vapor and the liquid–liquid interfaces near criticality because these two systems fall in the same universality class. For three pure liquid–vapor interfaces and five low-molecular-weight binary liquid–liquid interfaces measured over a range of approximately two decades in reduced temperature, Schmidt and co-workers measure $\chi \cong 3.0 \pm 0.2$ (Schmidt and Moldover, 1993). The temperature scaling agrees with Eq. (25), but the theoretical prediction is 20% too high (similar to the predictions for the optical reflectivity data previously discussed). For three high-molecular-weight polymer mixtures, Schmidt and co-workers measure a similar temperature scaling, but with a slightly lower χ (Miles and Schmidt, 1990).

Two subsequent theoretical analyses have produced values of χ in agreement with experiment. Blokhuis and Bedeaux (1990, 1992) extended Eq. (25) by adding the effects of a bending modulus, κq^4 with $\kappa = \mu k_B T$, where μ is predicted to be universal at criticality. The amplitude is adjusted to the value $\mu = 1.1$ resulting in a value for χ in agreement with the ellipsometry data. An alternative approach by Bonn and Wegdam (1992) utilizes a q^4 term in a q-dependent surface tension to obtain similar agreement with the experimental results. Therefore, the ellipsometry measurements provide indirect support for the necessity of a q^4 term, due to either a q-dependent surface tension or an interfacial stiffness.

4.3 Nonclassical or Nondielectric Fluid Interfaces

4.3.1 Quantum Liquids As a result of the quantum statistics of liquid helium, the nature of the liquid–vapor interface is different from that for classical liquids. Calculation of the capillary-wave spectrum requires replacing the classical thermal occupation numbers by those given by Bose–Einstein statistics. On the basis of a theory for the capillary-wave modes given by Atkins (1953), Cole (1970) calculated the broadening of the $T = 0$ intrinsic interface due to the capillary modes. Density-functional theories by Stringari and Treiner (1987) and others (see Lurio *et al.*, 1993, for references) predict an asymmetric form for the ^{4}He liquid–vapor interface in which the decay of the density into the vapor phase is more rapid than the decay into the liquid phase.

Measurements of the profile have been made using atom scattering, ellipsometry, and x-ray reflectivity. The atom scattering is most sensitive to the outer, vapor part of the profile, and determination of the full profile into the liquid is difficult with this technique. Ellipsometry has been used to measure the overall width of the profile, though details of its functional form were not obtained.

Fits to x-ray reflectivity measurements are consistent with an asymmetric hyperbolic secant form given by

$$\frac{d\langle\rho\rangle_0}{dz} = \frac{C}{\exp(az/\sigma_0) + \exp(-bz/\sigma_0)}, \tag{26a}$$

with

$$a = 1 + \exp(-\eta), b = 1 + \exp(\eta), \tag{26b}$$

where σ_0 is a measure of the interfacial width, η represents the asymmetry of the interface ($\eta = 0$ corresponds to a symmetric profile), and $d\langle\rho\rangle_0/dz$ is the *intrinsic* profile at $T = 0$. This $T = 0$ profile is convoluted with the capillary-mode spectrum to analyze the data. The fitted profile consistent with the x-ray reflectivity closely matches the theoretical prediction of Stringari and Treiner (1987). The best fit obtained is an asymmetric profile, though these measurements cannot conclusively exclude the possibility of a symmetric profile. The $T = 0$ profile has a 90–10% width of 0.76 nm and is broadened by capillary waves to 0.92 ± 0.1 nm at 1.13 K, for example. As shown by Lurio *et al.* (1993), these x-ray reflectivity data are consistent with the interfacial profile width determined by Osborne (1989) using ellipsometry and with the outer vapor portion of the profile determined by Nayak *et al.* (1983) using atom scattering.

4.3.2 Liquid-Metal Surfaces As we have seen, the profile at the liquid–vapor interface for a dielectric fluid changes monotonically from the bulk liquid density to the bulk density of the vapor. This is a consequence of the approximate density independence of the intermolecular potential. In a liquid metal the particles are electrons and ions, while the vapor above the surface contains atoms or molecules, resulting in an interparticle potential for the liquid metal that is strongly density dependent and varies significantly across the interface. It is reasonable to expect that liquid–vapor interfaces of dielectric and metallic fluids are very different (a review of the older literature is given by Rice *et al.*, 1986).

Early theoretical work by Evans and others combined an effective Hamiltonian for the inhomogeneous liquid metal with the assumption of a monotonic density profile and determined that the liquid–vapor transition region is very narrow, smaller than an atomic diameter (Evans, 1974; Kumaravadivel and Evans, 1975; Evans and Kumaravadivel, 1976; Evans and Hasegawa, 1981; Hasegawa and Watabe, 1982). Relaxing the assumption of monotonicity, Rice and coworkers used computer simulations to predict that the liquid–vapor interface of the metals sodium, cesium, magnesium, and mercury is stratified for approximately three atomic diameters into the bulk (D'Evelyn and Rice, 1983a,b; Rice *et al.*, 1986; Harris *et al.*, 1987a; Gomez and Rice, 1994). Heuristically, this stratification occurs because the strong electron-density dependence of the pseudopotential plays the role of a confining wall that creates atomic layering in a manner analogous to atomic layering at a liquid–solid interface.

Until recently, only indirect experimental evidence for this stratification was available. As examples, ellipsometry, visible-light reflectivity, dynamic visible-light scattering, surface viscosity, and surface-plasmon dispersion measurements at the mercury surface yielded anomalous results that could, however, be explained with a structured liquid–vapor interface (see Sluis and Rice, 1983, for references). In addition, measurements on several metals of the surface-tension variation with temperature yielded a positive $d\gamma/dT$ over a range in temperature, indicating a negative excess surface entropy (White, 1966, 1971) [see Eq. (15)]. This is consistent with local atomic ordering in the interface not present in the bulk.

If stratification occurs at the interface, a peak in the x-ray reflectivity should be observed at $Q_z \cong 2\pi/d \cong 20$–$25\ \mathrm{nm}^{-1}$, where d is the layer spacing (approximately the atomic diameter of the liquid metal). Early x-ray reflectivity measurements on laboratory sources were unable to attain these high values of Q_z and provided only indirect evidence of stratification (Lu and Rice, 1978; Bosio *et al.*, 1984; Barton *et al.*, 1986; Thomas *et al.*, 1987). Recent synchrotron x-ray reflectivity measurements have reached these high values of Q_z and confirmed the existence of the interface stratification at the surfaces of pure liquid gallium and mercury (Magnussen *et al.*, 1995; Regan *et al.*, 1995). In gallium, the measured layering decays with a $1/e$ length of 3–4 atomic diameters and is broadened slightly by capillary waves, in essential agreement with the general predictions from simulations of other liquid metal interfaces (simulations for the gallium interface have not been published). The interfacial width of the top layer with the vapor is approximately 0.087 nm, in agreement with values calculated solely from the surface tension and the resolution of the x-ray measurements. An additional contribution to the interfacial width from an intrinsic profile is not necessary. Similar synchrotron x-ray reflectivity measurements from the surface of mercury yield results in qualitative agreement with the predictions from simulation (Magnussen *et al.*, 1995).

Rice and co-workers (1986) have also predicted the behavior of the transverse structure function, i.e., the radial distribution function within the plane of the interface. In the point local-density approximation, the transverse structure function at a height z in the inhomogeneous interfacial region is given by the corresponding structure function in a homogeneous liquid at the same temperature and density. Because of the strong variation of density with height z, this approximation predicts a strong dependence of the transverse structure function in the inhomogeneous region of the interface on the position normal to the interface. An alternative approximation introduced by Fischer and Methfessel (1980) for hard-sphere liquids predicts the structure function in an inhomogeneous liquid to be that of the homogeneous liquid at the same temperature and at a density that corresponds to averaging over regions of one sphere diameter about a point in the inhomogeneous liquid. This leads to a greatly reduced dependence of the transverse structure function on position in the interface (Rice, 1987). This reduction is a consequence of the fact that the longitudinal structure at the interface is on the same length scale, the atomic diameter, as the averaging. Note that these considerations lead to the prediction that the liquid–vapor interface of dielectric liquids (which has inhomogeneities in the longitudinal structure on length scales of several atomic diameters) should exhibit a sizable variation in the transverse structure function. This prediction has not been subject to experimental verification (Flom *et al.*, 1992).

Recent measurements using x-ray grazing-incidence diffraction of the transverse structure function at the liquid–vapor gallium interface by Flom *et al.* (1992) are consistent with the prediction of the Fischer–Methfessel approximation and indicate that there is no measurable difference between the transverse structure function in the interface and the bulk structure function. These measurements are limited by the weak sensitivity to the topmost layer because the x rays probe a depth of ~5 nm, thereby averaging the structure function over this region. Unambiguous measurements of the transverse structure function at the interfaces of metallic and nonmetallic liquids await further experimental investigation.

In the case of liquid-metal alloys for which one of the components preferentially segregates at the interface, the pseudopotential is dependent upon both density and composition. As expected from the Gibbs adsorption equation [Eq. (15)], simulations on a Cs:Na alloy indicate that the lower-tension component, Cs, is preferentially adsorbed at the interface. In contrast to adsorption at a dielectric-mixture liquid–vapor interface for which the excess surface concentration is expected to decay monotonically over several atomic distances, the Cs formed essentially a single layer at the interface with subsequent modulations into the bulk alloy fluid similar to those expected for a pure metal (Harris *et al.*, 1987b). This view of the liquid-metal interface is supported by recent x-ray reflection and grazing-incidence diffraction experiments on a Bi-doped (~0.2%) Ga sample for which the Bi forms a segregated almost complete monolayer at the interface. The liquid-type transverse structure function of the Bi is similar to that expected for Bi supercooled by 271 °C (the transverse structure function was measured at 36 °C and the freezing temperature of Bi is 307 °C!) (Flom *et al.*, 1993; Lei *et al.*, 1996).

4.4 Complex-Fluid Interfaces

Complex fluids often exhibit more complex interfacial phenomena including layering, adsorption, and wetting, to name a few. In this section interfacial structure in surfactant solutions, long-chain liquids such as alkanes, and liquid crystals is used to illustrate the variety of phenomena studied. In this discussion, we concentrate on experimental results from x-ray or neutron scattering that directly probe these interfacial structures.

4.4.1 Microemulsions Although water and oil do not mix to an appreciable extent, the addition of a small amount of amphiphilic surfactant allows the three components to form a single phase. The mechanism for mixing is usually the formation of internal interfaces that partition the water and oil microscopically. Examples of these internal structures are micelles that consist of droplets of oil coated by surfactants and surrounded by water (this phase is denoted a droplet microemulsion) or large random sheets of surfactant that separate microscopic regions of oil and water (denoted a bicontinuous microemulsion). On variation of the relative composition and the temperature, these ternary mixtures often form three phases consisting of a middle-phase microemulsion sandwiched (by gravity) between the heavier water-rich phase and the lighter oil-rich phase. In the single-phase microemulsion the microemulsion-vapor (or -solid) interface can be studied; in the three-phase system the microemulsion-oil (or -water) interface can be studied.

In the three-phase system, wetting of the oil–water interface by the microemulsion can be discussed in terms of an effective interface potential of the oil-microemulsion interface with the microemulsion-water interface. For short-range forces, the effective interaction between these interfaces a distance d apart $V(d) \rightarrow \cos(kd + \phi)\exp(-d/\xi)$, in the asymptotic limit when d is large (ϕ is an unimportant phase) (Gompper and Schick, 1990a). The effective interface potential exhibits oscillations similar to those in the bulk phase, which represent locally structured microscopic regions of surfactant sheets separating oil and water. The exponential decay of this interaction mirrors the short-range character of the bulk structure.

Importantly, the interaction potential is influenced by the structure at the interfaces. Lattice models utilizing short-range forces predict the existence of nonmonotonic concentration profiles normal to the oil-microemulsion and microemulsion-water interfaces. This structure mimics the structure in the bulk microemulsion and is predicted, for short-range forces, to vary as $f(z) \sim \sin(kz) \times \exp(-z/\xi)$, where k and ξ are expected to take the same values as the bulk parameters (Dawson, 1987; Gompper and Schick, 1989, 1990a, b).

An important prediction of the lattice models is the nonmonotonic interfacial profile, which plays a role in determining the wetting properties of the microemulsion. Historically, Meunier (1985) used ellipsometry to study the structure at the oil-microemulsion and microemulsion-water interfaces of a five-component mixture. He concluded that "On the microemulsion side of the film we find a perturbed zone, the thickness of which is comparable with the size of the structure in the bulk."

Zhou *et al.* (1992) used neutron reflectivity to study the microemulsion-*vapor* interface of mixtures of the surfactant tetraethylene glycol monodecyl ether ($C_{10}E_4$), D_2O, and octane in the one-phase microemulsion region of the phase diagram. These measurements are consistent with the form of the interfacial profile given above, $f(z) \sim \sin(kz)$

$\times \exp(-z/\xi)$, with the surface and bulk values of k and ξ in agreement.

D. D. Lee *et al.* (1995) have made similar neutron-reflectivity measurements at the microemulsion–*solid silicon* interface for the same one-phase microemulsion system in the same region of the phase diagram. They measured the profile to be of the form given above; however, the surface and bulk values of k and ξ were not in agreement. Measurements as a function of temperature indicated that the surface values, k_s and ξ_s, varied in a systematic manner, while the bulk values were essentially constant. The authors hypothesize that these effects are due to the influence of the spontaneous curvature of the amphiphilic layers on the surface profile.

The microemulsion-oil (or -water) interfaces have an ultralow surface tension, measured to be as small as 1/10 000 of the pure water–oil interfacial tension (Fleming and Vinatieri, 1981; Chatenay *et al.*, 1985; Lee *et al.*, 1990). This low tension can be understood in terms of an unbinding transition of the near-surface lamellar structure (Gompper and Schick, 1994).

Because of the small interfacial tension, it is expected that the oil–microemulsion and microemulsion–water interfaces will be rough with large-amplitude thermal fluctuations. A similar expectation holds for a (out-of-equilibrium) surfactant-monolayer–covered oil–water interface as recently investigated. L. T. Lee *et al.* (1991) used a thin (~300 nm) layer of oil on top of a surfactant-monolayer–covered subphase of water. Neutron reflectivity was used to probe an octane–($C_{10}E_4$ monolayer)–water interface. Analyzing the overall drop in reflected intensity as in Eq. (20), they showed that their neutron reflectivity data are consistent with an interfacial roughness of 9 nm, as determined from their previous interfacial tension measurements using surface light scattering (L. T. Lee *et al.*, 1990). This roughness amplitude is much larger than the molecular lengths of the three components and is consistent with the presence of thermally excited surface waves.

McClain *et al.* (1994) used x-ray reflectivity and x-ray surface diffuse scattering to study a triethylene glycol monooctyl ether (C_8E_3) monolayer at a decane–water interface. In this case, the monolayer was formed by removing most of the nonwetting middle-phase microemulsion from a three-phase decane, water, and C_8E_3 solution, leaving a small amount of microemulsion in equilibrium with a C_8E_3 monolayer covering most of the interface. The use of diffuse scattering and reflectivity allowed for the surface tension to be determined independently from the interfacial width. Capillary-wave theory with a step-function intrinsic profile was used to fit their data and revealed the presence of large surface fluctuations (8.5-nm interfacial width).

Within the context of Ginzburg–Landau theories it was expected that the local interfacial density profile of the (oil-rich)–(water-rich) interface could be approximated by the mean-field profile for an (oil-rich)–(water-rich) interface covered by a surfactant monolayer (Gompper and Kraus, 1993). However, the microemulsion–water and oil–microemulsion interfaces are expected to be more complicated, with a nonmonotonic interfacial profile that will be strongly distorted by the interfacial curvature (Gompper and Kraus, 1993). These predictions have yet to be confirmed experimentally.

The first x-ray scattering (reflectivity and surface diffuse scattering) measurements from an equilibrium microemulsion–oil interface were recently reported on a 2-butoxyethanol (C_4E_1), water, and decane system that has very weak bulk structure and, therefore, is not expected to have nonmonotonic interfacial profiles (Williams *et al.*, 1996). The measured interfacial roughness and interfacial tension are respectively $\sigma = 5.7$ nm [Eq. (20)] and $\gamma = 0.14$ mN/m. This interfacial roughness is much larger than the largest molecule (~0.9 nm). No evidence for a nonmonotonic profile was reported; however, the range in Q_z was not large enough to detect it, if present.

Related structural measurements at the vapor interface of droplet microemulsions have been made (see Langevin, 1992, for a review of the optical measurements). Here we mention an x-ray reflectivity measurement by Schwartz *et al.* (1988) on the AOT (sodium di-2-ethylsulfosuccinate), D_2O, and decane system that has spherical micelles in the bulk (Kotlarchyk *et al.*, 1984; Huang and Kotlarchyk, 1986). Considering the planar symmetry of the interface, two possibilities are likely for the surface structure of this system:

1. one or more surfactant layers at the interface followed by a transition zone leading into the bulk fcc ordering of micelles or
2. extension of the fcc-ordered micelles directly up to the interface.

Schwartz *et al.* showed that the latter is true. The structure consists of two well-defined layers mimicking the surface of a fcc crystal, then decaying to the more random orientation of the bulk.

4.4.2 Alkanes and Alcohols The surface tension of most materials decreases with increasing temperature, indicating a positive excess surface entropy [see Eq. (15)]. As discussed, some liquid metals have $d\gamma/dT > 0$, which indicates an additional ordering at the surface. Earnshaw and Hughes (1992) measured $d\gamma/dT$ for temperatures slightly above the melting points of the *n*-alkanes, C15–C18 [where C_n refers to $CH_3(CH_2)_{n-2}$-CH_3]. For all of these alkanes, $d\gamma/dT > 0$ immediately above the bulk melting transition with an abrupt change to $d\gamma/dT < 0$ approximately 2°–3° above the melting transition. Subsequently, Wu and co-workers (1993a,b,c) used x-ray reflectivity and in-plane grazing-incidence diffraction to demonstrate that the first-order transition occurring a few degrees above the bulk melting transition is a surface freezing transition in which a single layer at the surface orders. Prior to these measurements, surface ordering or freezing had been discovered in liquid crystals (discussed in Sec. 4.4.3). However, for most materials the tendency is for surface melting because of the excess surface entropy at a solid–vapor interface.

Wu *et al.* (1993a,b,c) demonstrated that the surface freezing occurs only for chain lengths of 14–50 carbon atoms. The x-ray scattering from the surface is well explained by the top, single layer of molecules being orientationally ordered normal to the interface and positionally ordered in a hexagonal lattice within the plane of the interface with correlation lengths exceeding several hundred nanometers. For longer chain lengths, $n > 30$, the molecules in the top layer are tilted toward their nearest neighbors. This top layer has the density and x-ray signature of a rotator phase found in bulk alkanes for which the molecules are free to rotate about the long molecular axis. Only the top layer is ordered until the temperature is lowered to the bulk melting temperature at which the entire sample freezes. Deutsch *et al.* (1995) have seen similar freezing of the top layer of *n*-alcohol liquids for even carbon numbers between 18 and 26. The surfaces of binary mixtures of *n*-alkanes exhibit an additional surface phase, a monolayer of crystalline alkane, if the difference in chain lengths, Δn, is large enough (Wu *et al.*, 1995).

Currently there is not a consensus on the theoretical explanation for this surface freezing. Leermakers and Cohen-Stuart (1996) used a lattice model to demonstrate orientational surface ordering due to a hypothesized greater surface affinity of the CH_3 moieties. Tkachenko and Rabin (1996) propose that the free energy of a top solid layer is reduced by strong fluctuations along the molecular axis while the layer still remains a solid. This free-energy reduction is not available to molecules in the bulk since these fluctuations will be suppressed by neighboring molecules. This mechanism allows the top layer to solidify while the bulk remains a liquid. They successfully fit two sets of data from the experiments of Wu *et al.*:

1. the shift of the surface freezing temperature from the bulk freezing temperature as a function of the chain length *n* and
2. the correction to the liquid-surface tension due to the existence of the ordered top layer as a function of chain length.

As pointed out by Tkachenko and Rabin, this mechanism for surface freezing is only appropriate for materials whose ordered bulk phases have a high degree of three-dimensional ordering with out-of-plane fluctuations suppressed. For that reason it is not expected to apply to smectic liquid crystals for which strong out-of-plane fluctuations in the bulk phase are suppressed at the surface. As discussed in the next section, surface ordering in liquid crystals takes a different form.

4.4.3 Liquid Crystals Liquid crystals exhibit complex ordering phenomena in the bulk that has been extensively reviewed (Litster and Birgeneau, 1982; Pershan, 1988; Brock *et al.*, 1989; de Gennes and Prost, 1993). Early measurements by Miyano (1979a,b) and Beaglehole (1982) showed that the molecular order near the surface differs from that in the bulk. Theoretical work by Gubbins (1986) demonstrated that small, nonspherical molecules preferentially orient at surfaces, although these effects for small molecules are much harder to detect experimentally. Extensive theoretical work has demonstrated a variety of surface transitions for the longer molecules typically considered to be liquid crystals (for an older review, see Sluckin and Poniewierski, 1986; more recent theoretical work is discussed in Somoza *et al.*, 1995, and del Río *et al.*, 1995). The surfaces of liquid crystals exhibit wetting transitions, critical adsorption, and orientational transitions. Here, we discuss representative measurements of a few of these phenomena.

Early measurements of complex surface phenomena that directly probed structure on the molecular length scale were made by Pershan, Als-Nielsen, and co-workers on the liquid–vapor interface of liquid crystals. X-ray and neutron reflection has been used to study the surfaces of thermotropic and lyotropic crystals (Pershan, 1989; Penfold and Thomas, 1990). Synchrotron x-ray sources have much higher intensity than neutron sources. This allows for larger wave-vector transfer for x-ray scattering and, consequently, higher spatial resolution. However, by isotopic substitution the neutron scattering-length density of different regions of the interface can be enhanced. This is particularly useful in probing the structure of water molecules near ordered alkane chains of surfactant tail groups for which the x-ray scattering contrast is weak. The combined use of these techniques promises to be very powerful.

Although several different liquid crystals have been used as model systems to study surface effects, this discussion will be restricted primarily to studies of the isomorphic series of cyanobiphenyl molecules referred to as *n*CB. The *n*CB molecule has two adjacent phenyl groups providing a rigid core attached on one side to a cyano group and on the other to an alkyl chain with n carbon atoms. Integral values of n refer to the pure compound while fractional values refer to mixtures of *n*CB and $(n + 1)$CB. In the bulk material the phase transitions of interest here are as follows (these transitions occur in the range of 30 °C $< T <$ 60 °C for $8 < n < 12$): For $n \gtrsim 9.55$ there is a first-order transition from the isotropic to the smectic-A phase as the temperature is lowered; at $n \cong 9.55$ the isotropic–nematic–smectic-A triple point occurs; for $9 < n \lesssim 9.55$, first-order transitions from the isotropic to the nematic and from the nematic to the smectic A occur as the temperature is lowered, while for $n < 9$ the same sequence occurs, except that the nematic–smectic-A transition is second order.

The general tendency of *n*CB and other liquid-crystal systems is to form layers of smectic phase at the liquid–vapor interface that gradually decay into the bulk (Pershan, 1989). This is in contrast to the single layer at alkane surfaces previously discussed. Similar phenomena are also seen at a liquid-crystal interface with a solid wall (Ocko, 1990; Kellogg *et al.*, 1995). For example, as the reduced temperature $t = (T - T_{IA})/T_{IA}$, measuring the deviation from the first-order bulk isotropic to smectic-A transition, is reduced from $t = 0.1$ to $t = 10^{-5}$, the number of smectic layers at the liquid–vapor interface of the isotropic phase of 12CB increases from 1 to ~6 or 7. This increase in the number of adsorbed smectic layers occurs at well-defined temperatures in steps of one layer. Similar phenomena are seen for 9.55CB, 10CB, and 11CB as well as for a related isomorphic series 12OCB, 14OCB, and 16OCB (for *n*OCB the alkyl chain in *n*CB is replaced by an alkoxy chain). Pershan and co-workers argue that these transitions are most likely incomplete wetting transitions with the saturation at two layers for 16OCB unambiguously indicating incomplete wetting. For the shorter-chain samples (9.55CB, 10CB, and 11CB) that are closer to the triple point, the transition from the surface layering to the bulk becomes progressively more continuous in temperature. Pershan and Braslau argue that at any particular temperature the number of surface layers is well defined. These data suggest the possibility of a roughening transition as the triple point is approached.

When approaching a second-order nematic to smectic-A transition, these systems exhibit critical adsorption of smectic-A layers at the free surface of the nematic phase. In this case the surface layering extends exponentially into the bulk with a decay length equal to $\xi_{\parallel}$, the bulk decay length for correlations normal to the smectic layers. At the bulk first-order nematic to smectic-A transition, a pretransition growth of smectic correlations in the nematic phase occurs. This growth is cut off at the length scale $\xi_{\parallel}(T_{\mathrm{NA}})$ because of the first-order transition. Measurements on 9.15CB and 9.3CB show that the surface correlation length $\xi(T)$ is slightly larger than $\xi_{\parallel}(T)$ with a steadily increasing, but not diverging, ratio $\xi(T)/\xi_{\parallel}(T)$ as $T \rightarrow T_{\mathrm{NA}}$. This does not appear to be a true wetting transition.

5. SOME OTHER SURFACE PHENOMENA

Here, we briefly mention a few areas of importance that space has not permitted us to discuss more fully.

The in-plane or transverse structure factor at the surface of liquid crystals is most easily studied on freely suspended liquid crystal films (similar to soap films). The film thickness can be varied from two molecular layers to microns. These films have a large surface-to-volume ratio, allowing for the study of phase transitions in two and three dimensions (including the dimensional crossover). Transmission optical and x-ray techniques have been used to study wetting and adsorption phenomena, including surface freezing and layering transitions (Swanson *et al.*, 1989), molecular alignment surface transitions, and thin-film and surface hexatic phases (including fundamental studies of melting; see Brock *et al.*, 1986).

Langmuir monolayers of insoluble surfactants at the liquid (generally water)–vapor interface have been studied for many years (Gaines, 1966; Ulman, 1991). Many theoretical and experimental techniques have been used to study these films. Early equation-of-state measurements established some of the basic concepts concerning molecular orientation at interfaces and the (typically) short-range nature of intermolecular interactions, and deduced the cross-sectional area of long-chain fatty-acid molecules (Harkins, 1917; Langmuir, 1917). More recent measurements using nonlinear optical techniques and x-ray and neutron scattering have been able to probe directly the longitudinal and transverse density distributions of these monolayers (Shen, 1989; Knobler, 1990; Penfold and Thomas, 1990; Als-Nielsen *et al.*, 1994). An extensive variety of monolayer solid phases have been recently discovered, including the existence of two-dimensional solid islands at very low densities where it was formerly believed that two-dimensional gas and liquid phases coexisted. These direct probes also allow for molecular-scale studies of the kinetics of phase transformations that are important for determining the equilibrium equation of state for these materials (Bommarito *et al.*, 1996).

Very thin liquid films bounded by one or more solid walls or filling porous solid materials have also been studied (Gelfand and Fisher, 1990; Israelachvili, 1992). Although the solid–liquid interface is discussed elsewhere in this Encyclopedia, there is one result of particular interest for liquid interfaces. The structure of a liquid surface of a very thin (≤10 nm) liquid film on a rough solid surface is very different from the bulk surface structure. For thin enough films, the roughness of the liquid–vapor interface is correlated with the underlying rough liquid–solid interface (Garoff *et al.*, 1989; Tidswell *et al.*, 1991). Andelman and co-workers explained this correlation in terms of the nonretarded van der Waals forces important at these small distances (Andelman *et al.*, 1988; Robbins *et al.*, 1991).

The thermal energy responsible for capillary waves is also responsible for a continual exchange of fluid and vapor molecules across the interface. This type of surface process is discussed in the article SURFACE PROCESSES. Recent experiments that directly explore the atomic exchange at liquid surfaces include atom scattering from a liquid surface (King *et al.*, 1994).

Extensive studies of liquid surfaces and a few recent studies at the liquid–liquid interface have been made with nonlinear optical techniques that are surface sensitive. Second-harmonic generation is sensitive to the nonlinear polarizability of the molecule and determines molecular orientations at fluid interfaces (Shen, 1989; Eisenthal, 1992; Naujok *et al.*, 1995). Sum-frequency generation can provide information on alkane chain disorder in interfacial molecules by distinguishing between *trans* and *gauche* conformations in the chain (Guyot-Sionnest *et al.*, 1987; Messmer *et al.*, 1995).

In addition to the computer simulations of liquid-metal surfaces previously mentioned, numerous simulations of aqueous interfaces have been made (recently reviewed by Pohorille and Wilson, 1993). These simulations have been used to study, for example, the orientation of water molecules at the pure water surface, the water structure in hydrated ions and adjacent to surfactants at interfaces, the interfacial density profiles at liquid–liquid interfaces (such as water–oil interfaces), the structure of amphiphilic monolayers and bilayers at interfaces, and the surface tension and surface potential. Many of these predictions can be tested experimentally. For example, the prediction for a water molecule at the water surface indicates that its dipole moment is in the plane of the surface with one hydrogen pointing toward the vapor and one toward the liquid. The orientational distribution is broad and slightly asymmetric, resulting in an excess net dipole moment pointing into the liquid. This prediction is consistent with second-harmonic generation studies of the interface by Eisenthal (1992).

Although this article has focused on the structure at interfaces between bulk phases, complex fluids often contain internal interfaces that separate microscopic regions. These materials can be understood in terms of the interactions between these fluctuating, internal interfaces, a viewpoint very different from classical solution chemistry. This field is reviewed by Gompper and Schick (1994) and by Safran (1994).

GLOSSARY

Adsorption: The surface excess density.

Capillary Waves: Interfacial waves whose return force is determined by surface tension. Often combined with gravity waves whose return force is determined by gravity.

Criticality: At a critical point characterized by the divergence of pair correlation functions.

Interface: The transition region between any two bulk phases in contact.

Interfacial Profile (Longitudinal Density Profile): Electron, molecular, or number density profile through and normal to the interface between two bulk phases.

Interfacial or Surface Tension: The interfacial (or surface) tension is given by the free energy required to take molecules from the bulk of the liquid and create a unit area of interface (or surface).

Surface: The liquid–vapor interface.

Wetting: The intervening of a third equilibrium phase between two other equilibrium phases.

INTRODUCTION

A molecule consists of the nuclei of its constituent atoms and an electron density distribution. Symmetry considerations are important practically everywhere that molecules are considered. Among different branches of science it is mostly chemistry that is concerned with molecules, but other disciplines such as physics, crystallography, materials science, molecular biology, spectroscopy, just to mention the most obvious ones, are intimately related.

When we talk about the symmetry of a molecule we mean the symmetry of the geometrical arrangement of the atomic nuclei. A molecule may be "very symmetrical" or may have no symmetry at all. The possibility of applying different physical techniques to study molecules depends on their symmetry just as many other properties.

Molecular symmetry is a basic characteristic of molecular structure, which, in turn, determines all physical, chemical, and biological properties of a molecular substance. A recent conspicuous example of the importance of molecular symmetry is the discovery of buckminsterfullerene, the C_{60} molecule of the truncated icosahedral shape. The discovery originated from a synergistic interaction of astrophysical and cluster research and opened a whole new field of fullerene science and technology. The discovery was preceded by a prediction of the superstable C_{60} structure purely on molecular symmetry considerations.

But what is symmetry? It is one of the fundamental concepts of science, extending also to the humanities and the arts (Hargittai, 1986, 1989; Hargittai and Hargittai, 1994; Weyl, 1952). In a broad sense it refers to harmony and proportion. In a strict sense, though, it means a one-to-one correspondence among parts of an object. The word it-

self comes from the Greek *symmetria*, meaning "the same measure." Thus, e.g., the common mirror symmetry occurs when two halves of a whole are each other's mirror images. The action that characterizes a *symmetry type* (e.g., mirror symmetry) is called a *symmetry operation* (e.g., reflection by a mirror). The tool (e.g., the *mirror*, or *symmetry plane*) by whose means the operation is performed is called a *symmetry element*. Another symmetry element is a *rotation axis*. Its *order* tells us how many times the original figure recurs during a complete rotation. The *elemental angle* is the smallest angle of rotation by which the original figure can be reproduced. Yet another type of symmetry is called *inversion*, and the corresponding symmetry element is the *inversion point* or *center of symmetry*. In this case equivalent positions are related along a line going through the center. Inversion can also be looked at as a consecutive application of two simple symmetry operations, namely, a twofold rotation followed by a reflection through a plane perpendicular to the twofold rotation axis. Sometimes a fourth symmetry element, the *mirror–rotation axis* (called also *improper axis*) is distinguished. The corresponding symmetry operation, mirror–rotation or improper rotation, consists of two steps, a proper rotation followed by a reflection through a plane perpendicular to the rotation axis. When the rotation is twofold this symmetry is the inversion. The first three basic symmetry elements are indicated in Figure 1.

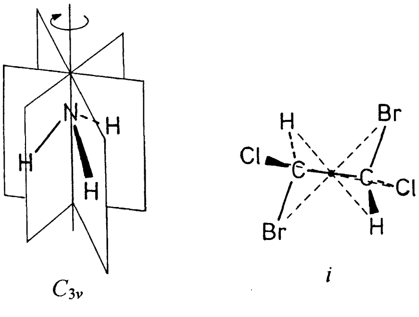

FIG. 1. Examples of molecules with (a) mirror symmetry (three mirror planes) and rotational symmetry (threefold rotation), and (b) inversion symmetry.

There are two large groups of symmetry, *point groups* and *space groups*. Point groups have at least one special point in the object or pattern that differs from all the others. It is also called a unique or singular point. Such a point or points remain unchanged during the symmetry operation. In space groups there is no unique point. Space groups are characterized by infinite repetition in one, two, or three directions in which case they are called one-, two-, or three-dimensional space groups, respectively. Extended arrays and networks of atoms and molecules, and, ultimately, crystal structures are described by space-group symmetries.

Molecules are finite with at least one singular point in their symmetry description. Thus point groups are applicable to them. There is no inherent limitation on the available symmetries for molecules, while severe restrictions apply to the symmetries of crystals. In fact, molecules occupy a more fundamental level in the hierarchy of structures than do crystals, and many crystals themselves are built from molecules.

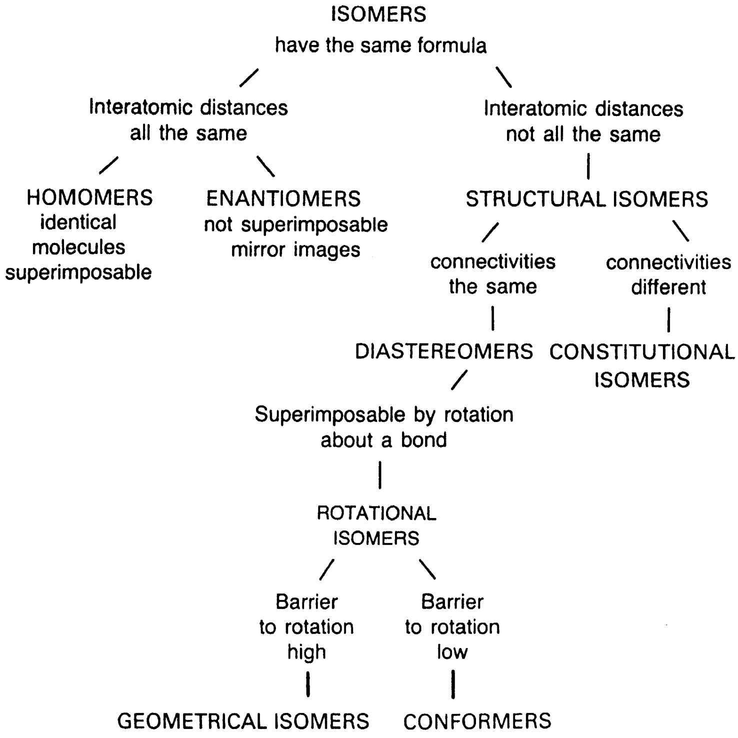
Molecules are never motionless. They are performing vibrations all the time. Molecular vibrations constitute relative displacements of the atomic nuclei with respect to their equilibrium positions and occur at all times and in all states of matter, including the crystalline state, and even at the lowest possible temperatures. The magnitude of molecular vibrations is not negligible at all; they amount to several percent of the internuclear distances. Typically, there are about 10^{12}–10^{14} vibrations per second.

Symmetry considerations are fundamental in any description of molecular vibrations, as will be seen later in detail. First, however, the molecular symmetries are discussed ignoring entirely the motion of the molecules. Various molecular symmetries are illustrated by their notations and examples. The most important techniques of the determination of the symmetry of molecules are enumerated with some comments, and a simple model is also discussed to gain some insight into the origins of the various shapes and symmetries of molecules. Our considerations are restricted, however, to relatively simple systems. Finally, the potentials of applications of the symmetry concept and description are demonstrated for the discussion of molecular vibrations, the electronic structure of molecules, and chemical reactions. For a more detailed account of the symmetry aspects of chemistry, we refer the reader to Hargittai and Hargittai (1995).

1. DESCRIPTION OF MOLECULAR SYMMETRY

Molecules with the same formula but in which the distances between corresponding atoms are not all the same are called *structural isomers* (Fig. 2). They are of two types. If their atomic connectivities are the same, they are *diastereomers,* and if their atomic connectivities are different, they are *constitutional isomers.* Connectivity is the order by which the atoms are linked through chemical bonds in the molecule. Some diastereomers can become superimposable by rotation about a bond, and they are called *rotational isomers.* Depending on the magnitude of the barrier to rotation, *geometrical isomers* (high barrier) and *conformers* (low barrier) are distinguished (see CONFORMATIONAL ANALYSIS).

Identical molecules have the same formula, the same atomic connectivity, and the same distances between corresponding atoms. Besides, they are superimposable (homomers). Enantiomers have the same formula, the same atomic connectivity, and the same distances between corresponding atoms, but they have no symmetry plane, and they are not superimposable. On the other hand, they are mirror images of each other. They are also called *chiral* (possessing handedness) pairs. Thus chirality is related to the absence of a certain symmetry element (the symmetry plane). This is a case of dissymmetry, a term first used by Louis Pasteur. Pierre Curie (1894) suggested a broad application of this term: "Dissymmetry creates the phenomenon" ["C'est la disymétrie qui crée le phénomène"], that is, a phenomenon is observable because of the absence of some symmetries from the system. The simplest chiral molecules are those in which a carbon atom is surrounded by four different atoms at the vertices of a tetrahedron. Molecules of many substances can be right-handed and left-handed. Many biologically important compounds exist in either the left-handed or the right-handed form in the living organism.



ISOMERS
have the same formula
Interatomic distances all the same
Interatomic distances not all the same
HOMOMERS identical molecules superimposable
ENANTIOMERS not superimposable mirror images
STRUCTURAL ISOMERS
connectivities the same
connectivities different
DIASTEREOMERS
CONSTITUTIONAL ISOMERS
Superimposable by rotation about a bond
ROTATIONAL ISOMERS
Barrier to rotation high
Barrier to rotation low
GEOMETRICAL ISOMERS
CONFORMERS

FIG. 2. The hierarchy of isomers.

For example, all naturally occurring amino acids are left-handed (except glycine). The two forms of a compound differing in handedness only may have very different properties. Figure 3 shows the formulas of the chiral pair of bitter and sweet asparagine.

1.1 Symmetry Notations

The so-called International or Hermann–Mauguin symmetry notations have been widely used in crystallography (see also CRYSTALLOGRAPHY). Another, older system, by Schoenflies, is generally used in spectroscopy to describe the molecular point-group symmetries. The Schoenflies notation has the advantage of succinct expression for even complicated symmetry classes combining various symmetry elements. The two systems are compiled in Table 1 for a selected set of symmetry classes. The set includes all point-group symmetries in the world of crystals, which are restricted to 32 classes. There are no restrictions on the point-group symmetries for individual molecules, and a few further, so-called *limiting,* classes are also listed in Table 1.

The Schoenflies notation for rotation axes is C_n, and for mirror–rotation axes the notation is S_{2n}, where n is the order of the rotation. The symbol i refers to the center of symmetry. Symmetry planes are labeled σ; σ_v is a vertical plane that always coincides with the rotation axis with an order of two or higher, and σ_h is a horizontal plane, which is always perpendicular to the rotation axis when it has an order of two or higher. The Hermann–Mauguin notations are not used for indicating molecular symmetries, and so they will only be mentioned briefly. Here n is used to indicate an n-fold rotation axis, m to indicate a mirror plane; a bar above a number indicates mirror–rotation axis, a slash after a number indicates rotation axis, and the letter m indicates that the reflection plane is perpendicular to the rotation axis.

Table 1. Examples of symmetry notations.

Hermann–Mauguin	Schoenflies

Limiting groups	
∞	C_∞
$\infty 2$	D_∞
∞/m	$C_{\infty h}$
∞mm	$C_{\infty v}$
∞/mm	$D_{\infty h}$

Point-group symmetries not listed in Table 1 may easily be assigned the appropriate Schoenflies notation by analogy. Thus, e.g.,

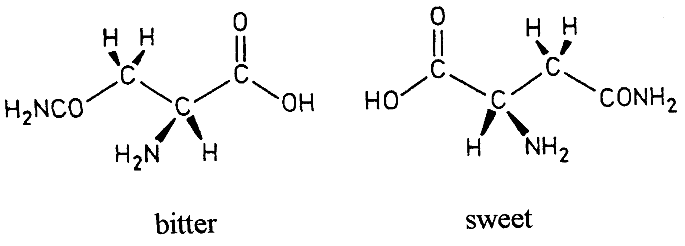

FIG. 3. Chiral pair of bitter and sweet asparagin.

C_{5v}, C_{5h}, C_7, C_8, etc. can be established. Such symmetries may well occur among real molecules.

1.2 Establishing the Molecular Point Group

Figure 4 shows a possible scheme for establishing the molecular point group. The symmetry of most molecules may be reliably established by this scheme.

First an examination is carried out whether the molecule belongs to some "special" group. If the molecule is linear, it may have a perpendicular symmetry plane ($D_{\infty h}$), or it may not have one ($C_{\infty v}$). Very high symmetries, such as tetrahedral, octahedral, or icosahedral, are easy to recognize. Each of the tetrahedral (T, T_h, and T_d) and octahedral (O and O_h) groups has four threefold rotation axes. Both icosahedral groups (I and I_h) require ten threefold rotation axes and six fivefold rotation axes. The molecules belonging to these groups have a central tetrahedron, octahedron, cube, or icosahedron.

If the molecule does not belong to one of these "special" groups, a systematic approach is followed. First, the possible presence of rotation axes in the molecule is checked. If there is no rotation axis, then it is determined whether there is a symmetry plane (C_s). In the absence of rotational axes and mirror planes, there may only be a center of symmetry (C_i), or there may be no symmetry element at all (C_1). If the molecule has rotation axes, it may have a mirror–rotation axis with even-number order (S_{2n}) coinciding with the rotation axis. For S_4 there will be a coinciding C_2, for S_6 a coinciding C_3, and for S_8, both C_2 and C_4.

In any case the search is for the highest-order C_n axis. Then it is examined whether there are n C_2 axes present perpendicular to the C_n axis. If such C_2 axes are present, then there is D symmetry. If in addition to D symmetry there is a σ_n plane, the point group is D_{nh}, while if there are n symmetry planes (σ_d) bisecting the twofold axes, the point group is D_{nd}. If there are no symmetry planes in a molecule with D symmetry, the point group is D_n.

Finally, if no C_2 axes perpendicular to C_n are present, then the lowest symmetry will be C_n; when a perpendicular symmetry plane is present, it will be C_{nh}; and when there are n coinciding symmetry planes, the point group will be C_{nv}.

1.3 Examples

Actual molecular structures are shown for various point groups in Fig. 5 in addition to those in Fig. 1, which correspond to the point groups (a) C_{3v} and (b) C_i. The Schoen-

FIG. 5. Examples of molecular symmetries.

flies notation is used. In some cases the characteristic symmetry elements are enumerated.

C_1: There are no symmetry elements except the onefold rotation axis, or identity, of course. C_1 symmetry is *asymmetry*, that is, the complete lack of any symmetry. An example is shown in Fig. 5.

C_n: One n-fold rotation axis. Example: Fig. 5 with C_3 symmetry.

C_i: Center of symmetry. Example: Fig. 1(b).

C_s: One symmetry plane. Example: Fig. 5.

C_{nh}: One n-fold rotation axis with a symmetry plane perpendicular to it. Example: Fig. 5 with a molecule of C_{2h} symmetry.

C_{nv}: One n-fold rotation axis with n symmetry planes that include the rotation axis. When n is even, there are two sets of symmetry planes. One set is rotated relative to the other set by $(180/n)°$. The angle between the planes within each set is $(360/n)°$. When n is odd, the angle between the symmetry planes is $(180/n)°$. Examples: Fig. 1 (C_{3v}) and Fig. 5 (C_{2v} and $C_{\infty v}$).

D_n: One n-fold rotation axis and n twofold rotation axes perpendicular to the n-fold axis. When n is even, there are two sets of twofold rotation axes. One set is rotated relative to the other set by $(180/n)°$. The angle between the axes within each set is $(360/n)°$. When n is odd, the angle between the twofold axes is $(180/n)°$. Example: Fig. 5 (D_2).

D_{nd}: One n-fold rotation axis with n twofold rotation axes perpendicular to it, and n symmetry planes. The angle between the twofold axes is $180/n°$. The symmetry planes include the n-fold axis and bisect the angles between the twofold axes. Example: Fig. 5 (D_{2d}, D_{3d}, and D_{4d}).

D_{nh}: There is one n-fold rotation axis, one symmetry plane perpendicular to it, and n symmetry planes that include the n-fold axis. When n is even, there are two sets of symmetry planes. One set is rotated relative to the other set by $(180/n)°$. The angle between the planes within each set is $(360/n)°$. When n is odd, the angle between the symmetry planes is $(180/n)°$. Example: Fig. 5 (D_{2h}, D_{3h}, and $D_{\infty h}$).

T: Three mutually perpendicular twofold rotation axes and four threefold rotation axes. The threefold axes all go through a vertex of a tetrahedron and the midpoint of the opposite face center. The twofold axes connect the midpoints of opposite edges of this tetrahedron.

T_d: In addition to the symmetry elements of symmetry T, there are six symmetry planes, each two of them being mutually perpendicular. Each of these symmetry planes contains two threefold axes. Example: Fig. 5.

O_h: Three mutually perpendicular fourfold rotation axes and four threefold rotation axes that are tilted with respect to the fourfold axes in a uniform manner, and a center of symmetry. Example: Fig. 5.

I_h: The most characteristic feature of this point group is the presence of six fivefold rotation axes. Example: Fig. 5.

2. DETERMINATION OF MOLECULAR SYMMETRY

In this section the most important methods are briefly introduced by which the symmetry of a molecule may be determined. Emphasis is placed on the accuracy of information and the main potentials and limitations of each method (Domenicano and Hargittai, 1992). In conclusion a qualitative model will be mentioned that has been used successfully for predicting the shapes and symmetries of large classes of simple molecules (Gillespie and Hargittai, 1991).

Some methods give only qualitative information on the general shape and symmetry of a molecule, while others give this information as part of a full, quantitative determination of molecular geometry.

2.1 Diffraction Techniques

These techniques are based on scattering phenomena in which a portion of the radiation changes direction without energy transfer. Diffraction effects arise from interference within the scattered radiation. This radiation may be electromagnetic, such as x rays, or very fast-moving small particles, such as electrons or neutrons. All three methods give quantitative information on molecular geometry.

X rays are scattered by the electron cloud of an atom. From the intensities and directions of the scattered beams of x rays, the three-dimensional pattern of electron-density distribution of the molecule can be deduced. From this the positions of the atomic nuclei can be determined, particularly for heavy atoms, while the accuracy is considerably lower for lighter atoms. Asphericity of the electron-density distribution of atoms introduces uncertainty into the determination of the nuclear position. Another limitation originates from the vibrational motion of the atoms relative to each other and the librational motion of the molecule as a whole. *X-ray diffraction* is primarily applied to crystalline solids, where the structure of a molecule may be affected by interactions with its neighbors.

In *neutron diffraction,* neutrons are scattered directly by the atomic nuclei, and they are scattered about as strongly by light atoms as by heavy atoms. Neutron diffraction is also primarily applied to crystalline solids. Its biggest disadvantage is that a suitable beam of neutrons may not be readily available.

The electrostatic interaction between matter and electrons is very strong in *electron diffraction.* The relative positions of the nuclei can be determined directly. Electron diffraction is applied to molecules in the gaseous state. An obvious limitation is that it is restricted to substances that have a vapor pressure of a few Torr at a temperature at which they are stable. The structure of only relatively simple molecules can be determined with this technique. The reliability of structural information may be enhanced considerably by using complementary data from other sources.

2.2 Spectroscopic Techniques

These are based on interactions that are accompanied by a transfer of energy between electromagnetic radiation and matter.

A rotating permanent dipole, such as a polar molecule in the gas phase, interacts with electromagnetic radiation if the frequency of the radiation is commensurate with the rotational frequencies of the dipole. The rotational frequencies of a molecule depend on the three moments of inertia. Depending on the symmetry of a molecule, spherical tops, symmetric tops, and asymmetric tops are distinguished, differing in the number of different values for the moments of inertia about three mutually perpendicular axes. For all, except the lightest, molecules the spectrum is in the microwave region, and so this spectroscopy is usually called *microwave spectroscopy*. It yields a complete geometry for simple molecules in favorable cases.

The most common determination of molecular symmetry is by *vibrational spectroscopy*. Displacement of the atoms during molecular vibrations leads to oscillations of the electric charge distribution in a molecule. The oscillating charge distribution interacts with the oscillating electric vector of the electromagnetic radiation. If the frequency of the vibration is commensurate with the frequency of the electromagnetic radiation, a quantum of energy may be absorbed by the molecule, raising it to a higher vibrational level. The vibrational frequencies of a molecule are generally in the range of 10^{14}–10^{12} Hz, and the corresponding frequencies are in the infrared region of the spectrum.

The vibrational frequencies of a molecule may also be obtained from the so-called Raman spectrum. When a molecule interacts with radiation of much higher frequency than its vibrational frequencies, it may absorb a quantum of radiation. This brings the molecule to an excited electronic state, but the molecule almost immediately re-emits a photon. The energy of the re-emitted photon may differ from the energy of the incident photon by a quantum of vibrational energy. The resulting spectrum is the Raman spectrum. A vibration will give rise to a Raman line if it leads to a change in the polarizability of the molecule.

2.3 Molecular Motion and Symmetry

Molecules are permanently in motion. The translational motion has no effect on the shape of the molecule. There is usually a slight centrifugal distortion due to rotation. The consequences of intramolecular vibrations may be truly important in the determination of molecular symmetry. As a consequence of molecular vibrations a molecule may appear to have a lower symmetry than the one ascribed to its equilibrium configuration in which the molecule is supposed to be motionless. Since the averaging over molecular vibrations is not the same in each technique, the apparent structures originating from different experiments may be different for the same molecule. Metal dihalide molecules, with their floppy nature, are typical examples. Thus, e.g., $MgCl_2$ is a linear molecule in its equilibrium state, and this is what we measure by spectroscopic techniques. Electron diffraction, however, because of vibrational averaging, "sees" the molecule as bent with a Cl–Mg–Cl angle of about 155°. The consequences of bending motion need to be eliminated via vibrational corrections in order to derive the equilibrium structure and symmetry of such a molecule.

An extreme but not uncommon case of intramolecular motion is the exchange, or permutation, of the atomic nuclei in the molecule. An example is the pseudorotation of the cyclopentane molecule. Pseudorotation refers to a process in which identical atoms permute among nonequivalent sites, and the net result looks like a rotation of the molecule.

The large-amplitude pseudorotation of the PF_5 molecule is called Berry pseudorotation. The fluorine nuclear magnetic resonance spectrum of PF_5 displays a single fluorine frequency, pointing to the equivalence of the fluorine sites. On the other hand, electron diffraction has established the trigonal bipyramidal structure of this molecule with D_{3h} symmetry in which the axial and equatorial sites are distinctly different. According to the Berry pseudorotation the axial pair of fluorines bends and forms a triangle together with one of the equatorial fluorines. The other two equatorial fluorines become the new axial atoms. There is a transition square pyramidal structure of C_{4v} symmetry in between the two trigonal bipyramidal structures (Fig. 6).

The Berry pseudorotation occurs fast compared with the nuclear magnetic resonance time scale, and slowly compared with the electron-diffraction time scale. Thus the understanding of the time-scale relationships between the magnitudes of interaction time in a physical measurement and the lifetime of a particular structure is fundamental to our understanding of the information on molecular symmetry from different physical techniques. Although, in principle, permutation of the nuclei may occur in all molecules, it happens billions of times a second in a PF_5 (D_{3h}) molecule, while it may happen only once or twice in 10^{15} years in a methane (CH_4) molecule (T_d).

2.4 Computational Techniques

The computational determination of molecular geometry, including molecular symmetry, has developed considerably in recent years as the capabilities of computers and the theoretical understanding of molecular structure have increased. It is possible, at least in principle, to compute all molecular properties, including symmetry, from the knowledge of the composition and atomic connectivity of the molecule by solving the corresponding Schrödinger equation. When this is done without invoking any additional information, the technique is called *ab initio* ("from the beginning"). These calculations yield the so-called equilibrium geometry corresponding to the minimum position of the molecular potential energy function. Thus it may be different from the average geometries yielded by the various experimental techniques. The computational determination of molecular symmetry, at least for the simplest systems, is as good today as that by the best experimental techniques.

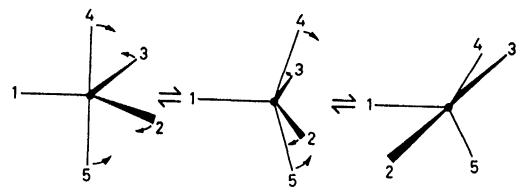

FIG. 6. Pseudorotation of a trigonal bipyramidal AX_5 molecule.

2.5 A Qualitative Model: VSEPR

In addition to the experimental and computational determination of molecular symmetry and structure, qualitative models are useful to predict molecular symmetry and its variations for series of substances. Such qualitative models are usually based on stressing a few effects, if not just one, in the complexity of intramolecular interactions and ignoring the rest. Thus it is always important to clearly delineate the scope of applicability of a qualitative model. A very successful and simple qualitative model of considerable predictive potential has been the so-called valence-shell electron-pair repulsion (VSEPR) model based on considerations of space requirements of the electron pairs.

It has been recognized that the number of electron pairs in the valence shell of atom A will determine the bond configuration of an AX_n molecule. If the valence shell contains unshared electron pairs as well, they also have to be considered. A formula such as AX_nE_m describes a molecule with a central atom A; n is the number of X ligands, meaning also that there are n A–X bonds, and m is the number of lone pairs in the valence shell of A. The arrangements of the electron pairs will always be such as to minimize their distances apart.

For two, three, four, five, and six electron pairs, i.e., when $n + m = 2, 3, 4, 5$, and 6, the arrangements of the electron pairs will be linear, trigonal planar, tetrahedral, trigonal bipyramidal, and octahedral. It is supposed here that the core beneath the valence shell has spherical symmetry, and the distribution of the electron pairs in the valence shell is the same as when mutually repelling points are distributed along the surface of the sphere. The power exponent in the expression of the potential energy of such repulsions is not known in our case of electron pairs in the valence shell. The utility of this model is in the invariance of the solutions to changes in the power exponent.

If all the electron pairs are bonds, the bond configuration will be the same as the arrangement of the electron pairs (Fig. 7). If one or more bonding pairs (bp) are replaced by lone pairs (lp), the bond configuration will be what corresponds to the original electron-pair arrangement being a part thereof (Fig. 7).

Establishing variations of molecular symmetry in series of substances, the relative spaces available at different sites in a given configuration, and the relative space requirements of bonds to various ligands, lone pairs vs. bonds, the multiplicity of bonds and other factors need additional consideration (Gillespie and Hargittai, 1991).

operation carried out on the molecule. The geometry of the nuclear arrangement in the molecule is such a property: A symmetry operation transforms the nuclear arrangement into another, which will be indistinguishable from the initial.

Dynamic properties, on the other hand, may change under symmetry operations. Molecular motion itself is a dynamic property, and since real molecules are never motionless, the symmetry properties of their motion may greatly influence their chemical behavior. The two main kinds of motion in a molecule are nuclear and electronic.

Dynamic properties can be either *symmetric* or *antisymmetric* with respect to the various symmetry operations of the molecular point group. Group theory (*q.v.*) is the mathematical apparatus for describing symmetry operations. The first step in the symmetry determination of dynamic properties is the selection of the appropriate basis for the representation. Appropriate here means the correct representation of the changes in the properties examined. In the investigation of molecular vibrations (Sec. 3.1), either Cartesian displacement vectors or internal coordinate vectors are used. In the description of the molecular electronic structure (Sec. 3.2), the angular components of the atomic orbitals are frequently used bases. Since the angular wave function changes its "sign" under certain symmetry operations, its behavior will be characteristic of the spatial symmetry of a particular orbital. Molecular orbitals can also be used as a basis of representation. Considerations of symmetry properties play a role in determining whether a quantum mechanical integral of the type $\int \psi_i$ op. $\psi_j d\tau$ is different from zero or not. This is important in such areas as selection rules for electronic transitions, chemical reactions, infrared and Raman spectroscopy, and other spectroscopies.

3.1 Molecular Vibrations

Vibration is a special kind of motion: the atoms of every molecule are permanently changing their relative positions at every temperature (even at absolute zero) without changing the position of the molecular center of mass. In terms of the molecular geometry these vibrations amount to continuously changing bond lengths and bond angles. (Molecular vibrations are also dealt with under the heading MOLECULAR SPECTROSCOPY.)

Symmetry considerations are instrumental in discussing and understanding molecular vibrations. Here we give only a short account on what kind of information can be deduced about the internal motion of the molecule from the mere knowledge of its point-group symmetry. For more detailed treatment we refer to monographs by Herzberg (1959), Wilson *et al.* (1955), and Hargittai and Hargittai (1995).

3.1.1 Normal Modes The seemingly random motion of molecular vibrations can always be decomposed into the sum of relatively simple components, called *normal modes of vibration.* Each of the normal modes is associated with a certain frequency. Thus for a normal mode every atom of the molecule moves with the same frequency and in phase. There are $3N - 6$ (for the linear case $3N - 5$) normal modes of vibration in a molecule.

The close relationship between symmetry and vibration is expressed by the following rule: Each normal mode of vibration forms a basis for an irreducible representation of the point group of the molecule. (For each point group the irreducible representations can be found in the so-called character tables; see GROUP THEORY). From the symmetry group of the molecule the symmetry species of the normal modes can be determined without any additional information.

For this purpose the so-called *Cartesian displacement vectors* are used as bases. The obtained reducible representation can be reduced to a sum of irreducible representations using the reduction formula (see GROUP THEORY). Subtracting those irreducible representations that correspond to translation and rotation (on the basis of character tables), the symmetry of the normal modes can be determined. For example, the water molecule has three normal modes of vibration. The molecular point group is C_{2v}, and two of the normal modes belong to the A_1 and one to the B_2 irreducible representation (Fig. 8) of this point group.

The normal modes can usually—though not always—be associated with a certain kind of motion. Those connected mainly with changes in bond lengths are the *stretch-*

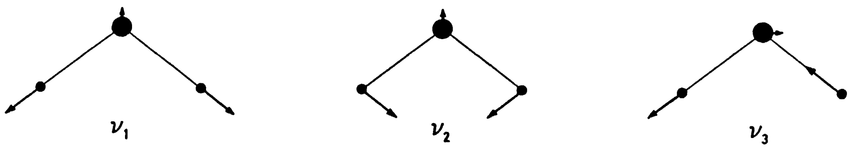

FIG. 8. Normal modes of vibration for the water molecule: ν_1, symmetric stretch (A_1); ν_2, bending (A_1); and ν_3, asymmetric stretch (B_2). The lengths of the arrows indicate the relative displacements of the atoms.

ing modes. The ones connected mainly with changes of bond angles are the *deformation modes*. These are mostly either in-plane or out-of-plane deformation modes. The simplest deformation mode is the *bending mode*. In case of water, one of the A_1- and the B_2-symmetry normal modes are stretching modes, and the other A_1-symmetry normal mode is a bending mode. The A_1-symmetry stretching mode is called the symmetric stretch, while the B_2 mode is the antisymmetric stretch (see Fig. 8).

3.1.2 Symmetry Coordinates The symmetry coordinates are symmetry-adapted linear combinations of the *internal coordinates*. The internal coordinates are the geometrical parameters of a molecule, and their displacement is used as a basis for representations. Symmetry coordinates can be generated from the internal coordinates by the use of the projection operator (see GROUP THEORY).

Both the symmetry coordinates and the normal modes of vibration belong to an irreducible representation of the point group of the molecule. A symmetry coordinate is always associated with one or another type of internal coordinate—that is, pure stretch, pure bend, etc.—whereas a normal mode can be a mixture of different internal coordinate changes of the same symmetry. For the water molecule, e.g., the symmetry coordinates are good approximations of the normal vibrations, and so their pictorial representation is the same.

The relationship between the symmetry coordinates and the normal vibrations can be established only by calculations called normal-coordinate analysis (see, e.g., Wilson *et al.*, 1955). These calculations necessitate further data in addition to the knowledge of molecular symmetry.

3.1.3 Selection Rules Depending on the symmetry of the molecule, not all normal modes will be observed in the infrared and Raman spectra because they do not all lead to a change in the dipole moment or in the polarizability of the molecule. In general, the number of bands observed in the infrared and Raman spectra of a molecule increases with decreasing molecular symmetry.

The considerations on the symmetries of the ground and excited states are instrumental in determining the selection rule for infrared spectroscopy: A fundamental vibration will be infrared active—i.e., appear as an absorption band in the infrared spectrum—if the corresponding normal mode belongs to the same irreducible representation as one or more of the Cartesian coordinates.

The selection rule for Raman spectroscopy can also be derived by similar reasoning. It says: A fundamental vibration will be Raman active if the normal mode undergoing the vibration belongs to the same irreducible representation as one or more of the components of the polarizability tensor of the molecule. These components are the quadratic functions of the Cartesian coordinates given in the fourth area of the character tables. The Cartesian coordinates themselves are given in the third area. Thus the symmetry of the normal modes of a molecule is sufficient information to tell what transitions will be infrared and what transitions will be Raman active. The normal modes of the water molecule belong to the A_1 and B_2 irreducible representation of the C_{2v} point group. Using merely the C_{2v} character table, it can be deduced that all three vibrational modes will be active in both the infrared and Raman spectra.

Since a particular normal mode may belong to different symmetry species in different point groups, its behavior depends strongly on the molecular symmetry. Just to mention one example, the ν_1 symmetric stretching mode of an AX_3 molecule is not infrared active if the molecule is planar (D_{3h} symmetry), i.e., it does not appear in the spectrum. It is infrared active and thus appears in the spectrum, however, if the molecule is pyramidal (C_{3v} symmetry). Vibrational spectroscopy is obviously one of the best experimental tools to determine the symmetry of molecules.

3.2 Electronic Structure of Molecules

Everything that counts in chemistry is related to the electronic structure of atoms and molecules (see ELECTRONIC STRUCTURE OF ATOMS AND MOLECULES). The formation of molecules from atoms, their behavior, and their reactivity all depend on their electronic structure. What is the role of symmetry in all this? In various aspects of the electronic structure, symmetry can tell us a good deal: why certain bonds can form and others cannot, why certain electronic transitions are allowed and others are not, and why certain chemical reactions occur and others do not.

3.2.1 Symmetry Properties of the Wave Function The symmetry properties of the electronic wave function and the energy of the system are two determining factors in chemical behavior. The relationship between the wave function characterizing the behavior of the electrons and the energy of the system—atoms and molecules—is expressed by the Schrödinger equation. In its general and time-independent form, it is usually written as

$$H\psi = E\psi, \tag{1}$$

where H is the Hamiltonian operator and E is the energy of the system.

With respect to the interchange of like particles (either nuclei or electrons), the Hamiltonian must be unchanged under a symmetry operation. This means that it belongs to the totally symmetric representation of the molecular point group.

A fundamental property of the wave function is that it can be used as basis for irreducible representations of the point group of a molecule. This property establishes the connection between the symmetry of a molecule and its wave function.

The electronic wave function of a one-electron system can be represented as a product of a radial and an angular component:

$$\psi_e = R(r)A(\Theta,\Phi). \tag{2}$$

The separation of the wave function into two parts is convenient since these two parts relate to different properties. The radial part determines the energy of the system and is invariant to symmetry operations. The angular part, on the other hand, says nothing about the energy of the system, but it can be altered by symmetry operations. The function $A(\Theta,\Phi)$ may have different signs (+ and −) in different spatial regions. A change in sign indicates a drastic change in the wave function. These signs might be thought of as signs of the amplitudes of the wave function. The places where the wave function changes sign are called *nodes*. The number of nodes is $n - 1$, where n is the principal quantum number.

The well-known shapes of some one-electron orbitals are presented in Fig. 9; these are, in fact, representations of the angular wave functions. Such representations are used commonly for illustrations because they describe accurately the symmetry properties of the wave function. In order to give the total wave function, however, they must be multiplied by an appropriate radial function.

What are the symmetry properties of an orbital? An orbital can be either symmetric or antisymmetric with respect to a certain symmetry operation. In Fig. 10 are shown the $d_{x^2-y^2}$ and p_z orbitals and their behavior under the inversion operation. The d orbital is transformed into itself by inversion; both the magnitude and the "sign" of the wave function will remain the same; it is symmetric with respect to inversion. The effect of the inversion operation on the p orbital is different: its magnitude does not change, but its "sign" does upon inversion; the p orbital is antisymmetric with respect to inversion. In the character tables, this is indicated by +1 for symmetric and −1 for antisymmetric behavior under each symmetry operation. The atomic orbitals (AOs) always belong to the same irreducible representations of the given point group as do their subscripts (x, y, z, xy, $x^2 - y^2$, etc.).

3.2.2 Construction of Molecular Orbitals A molecule is not simply a collection of its constituting atoms; rather, it is a system of atomic nuclei and a common electron distribution. Nevertheless, in describing the

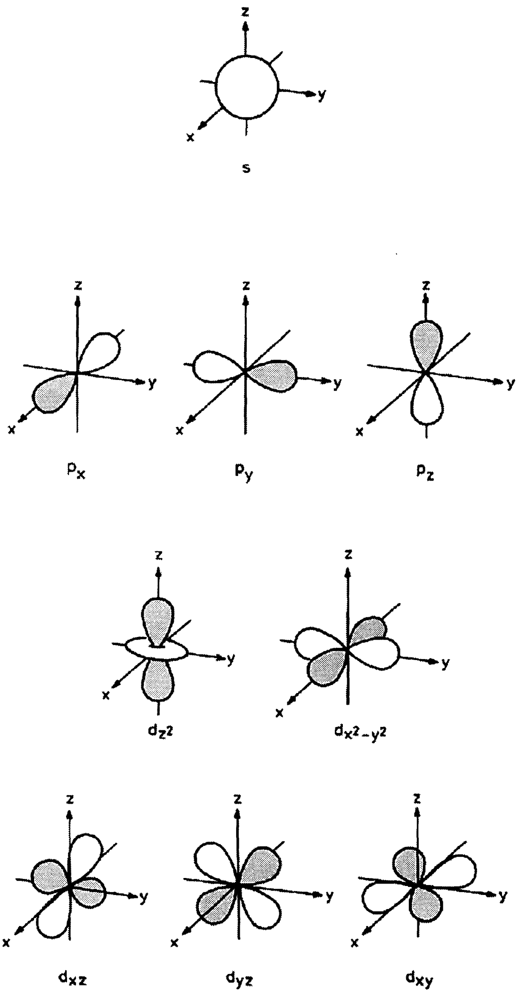

FIG. 9. Shapes of one-electron orbitals. They are representations of the angular wave function, $A(\Theta,\Phi)$.

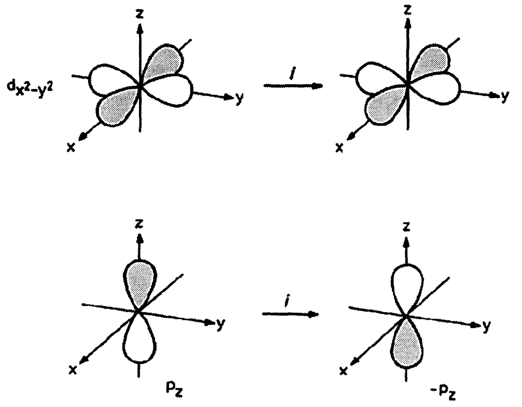

FIG. 10. The effect of inversion on the $d_{x^2-y^2}$ and p_z orbitals.

electronic structure of a molecule the most convenient way is to approximate the molecular electron distribution by the sum of atomic electron distributions. This approach is called the *linear combination of atomic orbitals* (LCAO) method. The orbitals produced by the LCAO procedure are called *molecular orbitals* (MOs).

Although both AOs and MOs are one-electron wave functions, the shape and symmetry of the MOs are different from those of the AOs of the isolated atom. Molecular orbitals extend over the entire molecule, and their spatial symmetry must conform to that of the molecular framework.

When constructing MOs from AOs, there may be a large number of possible linear combinations of AOs. Many of these linear combinations, however, are unnecessary. Symmetry is instrumental as a criterion in choosing among them. All those linear combinations must be eliminated that do not belong to any irreducible representation of the molecular point group. The reverse of this statement constitutes the fundamental principle of forming MOs: Each possible MO must belong to an irreducible representation of the molecular point group. Another equally important rule for the construction of MOs is that only those AOs can form a MO that belong to the same irreducible representation of the molecular point group.

When AOs are used for MO construction, their symmetry must be considered in the symmetry group of the particular molecule. A MO can only be formed from AOs of the same symmetry, and the symmetry of this new MO will be the same as that of the component AOs.

In addition to complying with symmetry rules, successful MO construction requires certain energy conditions. Two AOs will only combine for a MO if their energies are not too different.

3.2.3 Electronic States The orbitals and electronic configurations are useful descriptions. In many-electron systems, however, the energy of the orbitals loses its physical meaning, and only the energies of the (ground and excited) states are real. It is these states that are described by the total electronic wave functions. Electronic transitions, in fact, represent changes in the state of an atom or a molecule and not necessarily in the electronic configurations.

The symmetry of the electronic states can be determined from the symmetry of the occupied orbitals. There are two different cases:

1. States with fully occupied orbitals. An electronic configuration in which all orbitals are completely filled possesses only one electronic state, and it will be totally symmetric.
2. States with partially occupied orbitals. The completely filled orbitals are ignored (for reasons described above), and the symmetry of the state will be given by the direct product of the partially filled orbitals.

3.3 Chemical Reactions

The first application of symmetry considerations to chemical reactions were the Wigner–Witmer rules that are concerned with the conservation of spin and orbital angular momentum in the reaction of diatomic molecules. The real breakthrough in recognizing the role that symmetry plays in determining the course of chemical reactions has occurred only recently, mainly through the activities of Woodward and Hoffmann (1970), Fukui (1975), Bader (1962), Pearson (1976), and others. For other than symmetry aspects of chemical reactions, see CHEMICAL REACTIONS.

Symmetry phenomena may play as important a role in chemical reactions as they do in the construction of molecular orbitals or in molecular spectroscopy. It is even possible to make certain symmetry-based "selection rules" for the "allowedness" and "forbiddenness" of a chemical reaction, just as is done for spectroscopic transitions.

There are, of course, limitations to the applicability of symmetry rules for chemical reactions. Symmetry rules can usually be applied to comparatively simple reactions, the so-called *concerted reactions.* In a concerted reaction all relevant changes occur simultaneously; the transformation of reactants into products happens in one step with no intermediates.

The statement that a chemical reaction is "symmetry allowed" or "symmetry forbidden" should not be taken literally. When a reaction is symmetry allowed, it means that it has a low activation energy. This makes it possible for the given reaction to occur, though it does not mean that it always will. There are other factors that can impose a substantial activation barrier. Such factors may be steric repulsions, difficulties in approach and unfavorable relative energies of orbitals. Similarly, "symmetry forbidden" means that the reaction, as a concerted one, would have a high activation barrier. However, various factors may make the reaction still possible; for example, it may happen as a stepwise reaction through intermediates. In this case, of course, it is no longer a concerted reaction.

Most of the symmetry rules explaining and predicting chemical reactions deal with changes in the electronic structure. However, a chemical reaction is more than just that. Breakage of bonds and formation of new ones are also accompanied by nuclear rearrangements and changes in the vibrational behavior of the molecule.

As has been shown previously, both the vibrational motion and the electronic structure of the molecules strongly depend on symmetry. This dependence can be fully utilized when discussing chemical reactions. It is not only the reactant and product molecules whose electronic structure and vibrations can be described with the help of symmetry. Even more importantly, certain symmetry rules can be applied to the *transition state* between the reactants and products.

3.3.1 Reaction Coordinate The changing nuclear positions during the course of a reaction are collectively described by the term *reaction coordinate.* In simple cases we may assume that the chemical reaction is dominated by one of the normal modes of vibration, and thus this vibrational mode is the reaction coordinate. All the other normal vibrations are at their optimum value, so their energy is at minimum. Therefore, this reaction path can be taken as a *minimum-energy path.* Concerning symmetry properties, the reaction coordinate belongs to the totally symmetric irreducible representation of the molecular point group except at a maximum or at a minimum.

3.3.2 Electronic Structure A chemical reaction is a consequence of interactions between molecules. Before a reaction takes place (i.e., while the reacting molecules are still far apart), their electron distribution is unperturbed. When they approach each other, their orbitals begin to overlap, and distortion of the original electron distribution takes place. There are two requirements for a constructive interaction between molecules: symmetry matching and energy matching. These two factors can be treated in different ways. The approaches of Fukui (1975) and of Woodward and Hoffmann (1970) differ somewhat.

3.3.2.1 Frontier Orbitals: HOMO and LUMO. A successful chemical reaction requires both energy and symmetry matching between the MOs of the reactants. The requirements are essentially the same as in case of constructing MOs from AOs. Only orbitals of the same symmetry and comparable energy can overlap successfully. The most significant interactions can be expected between the highest occupied molecular orbital (HOMO) of one molecule and the lowest unoccupied molecular orbital (LUMO) of the other. The concept of these so-called *frontier orbitals* simplifies the MO description of chemical reactions enormously, since only these MOs of the reactant molecules need to be considered.

3.3.2.2 Conservation of Orbital Symmetry. Within this approach a correlation diagram is constructed from the orbitals of the reactants and the product(s). On one side of the diagram the approximate energy levels of the reactants are drawn, while on the other side those of the product(s) are indicated. A particular geometry of approach must be assumed. Furthermore, the symmetry properties of the molecular orbitals must be considered in the framework of the point group of the transition structure. Those molecular orbitals are taken into account that are associated with bonds that are broken or formed during the chemical reaction. Energy levels on the two sides of the diagram are to be connected in such a way that the so-called *noncrossing rule* is not violated. According to this rule, two orbitals of the same symmetry cannot intersect.

3.3.2.3 State Correlation. The correlation diagram discussed above refers to molecular orbitals. Since electronic transitions occur physically between electronic states, the correlation of these states is of interest. The rules for the state correlation diagrams are the same as for the orbital correlation diagrams: Only states that possess the same symmetry can be connected. Figure 11 shows the state correlation diagram for ethylene dimerization.

An obvious connection between states that possess the same electronic configuration would be the one indicated by the dashed lines in the figure. This does not occur, however, because states of the same symmetry cannot cross. Instead of crossing, when two states are coming too close to each other they will turn away, and so the two ground states, both of A_g symmetry, and also two A_g-symmetry excited states will each mutually correlate. The full line connecting the two ground states in Fig. 11 indicates that there is a substantial energy barrier to the ground-state-to-ground-state process; this reaction is said to be "thermally forbidden."

Consider now one electron in the reactant system excited photochemically to the B_{2g} state. Since this state correlates directly with the B_{2g} state of the product, this reaction does not have any energy barrier and may occur directly. It is said that the reaction is "photochemically allowed." Indeed, it is an experimental fact that olefin dimerization occurs smoothly under irradiation.

This observation can be generalized. If a concerted reaction is thermally forbidden, it is photochemically allowed and vice versa; if it is thermally allowed, then it is photochemically forbidden.

3.3.2.4 Generalized Woodward–Hoffmann Rules. *Cycloaddition.* The reaction between two molecules is thermally allowed

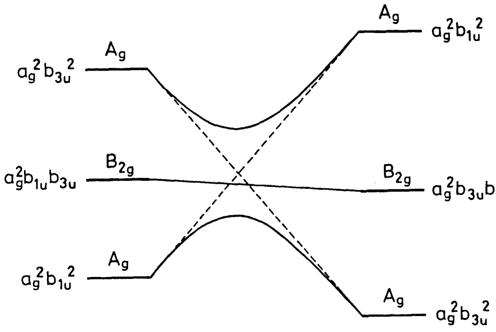

FIG. 11. State correlation diagram for the ethylene dimerization.

if the total number of electrons in the system is $4n + 2$ (n is an integer) and both components are either suprafacial or antarafacial. If one component is suprafacial and the other is antarafacial, the reaction will be thermally allowed if the total number of electrons is $4n$.

Electrocyclic reactions. The rules are similar to those given above. A disrotatory process is thermally allowed if the total number of electrons is $4n + 2$, and a conrotatory process is allowed thermally if the number of delocalized electrons is $4n$. For a photochemical reaction, both sets of rules are reversed.

ACRONYMS

AO: Atomic orbital.

HOMO: Highest occupied molecular orbital.

LCAO: Linear combination of atomic orbitals.

LUMO: Lowest unoccupied molecular orbital.

MO: Molecular orbital.

VSEPR: Valence-shell electron-pair repulsion.

GLOSSARY

Ab Initio Calculations: Nonempirical determination of molecular properties by computational techniques.

Antisymmetry: The symmetry of opposites.

Asymmetry: The absence of any symmetry.

Buckminsterfullerene: C_{60} molecule of truncated icosahedral shape.

Chiral: Not superimposable with its mirror image.

Chiral Pairs: Enantiomeric molecules.

Concerted Reaction: A reaction in which relevant changes occur simultaneously; the transformation of reactants into products happens in one step.

Connectivity: The order by which the atoms are linked by chemical bonds in the molecule.

Constitutional Isomers: Molecules having the same sum formula but different connectivities.

Dissymmetry: The absence of certain symmetry.

Elemental Angle: The smallest angle of rotation by which the original figure can be reproduced during rotation.

Enantiomers: Molecules that have the same formula, same connectivity, and same distances but have no symmetry plane and are not superimposable but are mirror images of each other.

Frontier Orbitals: The highest occupied molecular orbitals (HOMO) and lowest unoccupied molecular orbitals (LUMO) in a molecule.

Internal Coordinates: The geometrical parameters of a molecule (bond lengths, bond angles, and angles of torsion).

Inversion Point: The point remaining invariant under the operation of inversion. Each pair of points equivalent to one another under the operation can be joined by a straight line passing through the point.

Molecular Vibrations: Relative displacements of the atomic nuclei with respect to their equilibrium positions in the molecule.

Normal Modes of Vibration: Simple vibrations whose sum make up the seemingly random motion of molecular vibrations.

Order of Rotational Symmetry: The integer telling how many times the original figure recurs during a complete rotation.

Point Groups: Those symmetry groups for which there is at least one unique point remaining unchanged during a symmetry operation.

Pseudorotation: A process in which identical atoms permute among inequivalent sites and the net result looks like a rotation of the molecule.

Reaction Coordinate: Collective description of the changing nuclear positions in molecules during a chemical reaction.

Rotational Isomers: Diastereomers that can be superimposed by rotation about a bond.

Selection Rules: Rules that describe which normal modes will be active in the infrared and Raman spectra.

Space Groups: Symmetry groups that have no unique point.

Structural Isomers: Molecules with the same sum formula but in which the distances between corresponding atoms are not all the same.

Symmetry Coordinates: Symmetry-adapted linear combinations of internal coordinates.

Symmetry Element: The *tool* by whose means a certain symmetry operation is performed.

Symmetry Notations: A shorthand description of all symmetries.

Symmetry Operation: The *action* that characterizes a symmetry type.

VSEPR Model: Qualitative determination of molecular shape based on the space requirements of electron domains in the valence shell of the central atom of a molecule.

INTRODUCTION

Synchrotron radiation (SR) is an outstanding tool for materials science and life sciences. After the usefulness of SR was shown by the early experiments, many efforts have been devoted to develop new technologies for SR storage rings including compact storage rings for industrial use, insertion devices for brighter beams, advanced monochromators for higher resolution, beamlines for higher spatial resolution, and experimental apparatus for versatile applications. SR is extensively used for investigating chemical, biological, geological, and physical systems, and for characterizing new materials.

In materials science and technology, new materials analysis techniques have been developed utilizing unique properties of SR. Extended x-ray absorption fine structure (EXAFS), surface x-ray diffraction, high–energy-resolution photoelectron spectroscopy, and spatially resolved chemical analysis with a microbeam are good examples. These techniques have been employed to characterize trace impurities and surface/interface structures of semiconductors, which dominate the properties of new electronic and optoelectronic devices. Furthermore, SR has been utilized to fabricate structures with 0.1-μm lateral resolution (by x-ray lithography) and atomic-scale vertical resolution (by photochemical reaction). Atomically controlled film growth by means of real-time monitoring with SR is now possible.

In life sciences, SR is regarded as a key tool for analyzing the structures of newly developed small crystals of protein and other giant molecules using an x-ray microbeam. In this field, structure determination used to be very difficult because of the difficulty of

making crystals large enough for conventional x-ray diffraction. The structure determination of huge viruses such as the cancer virus SV40 of 500-Å diameter has become possible as a result of the high intensity and collimation at short wavelengths. The structure information is well correlated with medical or chemical properties. Nowadays the medical industry is showing great interest in these techniques. SR-induced reactions have reportedly been utilized to produce new proteins by selective synthesis. Further improvements can be expected when much brighter SR beams from third-generation SR sources are used.

Within the last decade many electronics companies have established their own proprietary beamlines for mainly x-ray lithography and crystallographic analysis of semiconductor materials. On the basis of the success of x-ray lithography, many compact storage rings have been constructed for device fabrication processes, where an SR ring is regarded as an indispensable process apparatus like an ion implanter, chemical vapor deposition (CVD) apparatus, or ion-etching apparatus. Thus, in order to foresee future trends in SR research, the technological prospects should be also better understood.

1. PROPERTIES OF SYNCHROTRON RADIATION

When charged particles are forced to move at speeds close to the speed of light in a circular orbit in vacuum, photons are emitted in the forward direction tangential to the orbit. This radiation is called synchrotron radiation. The radiation from the Crab Nebula has the same origin as SR.

The properties of SR sources are unique, producing radiation with high brightness, a high degree of linear polarization, a high degree of collimation in the forward direction, and pulse widths of about 200 ps and durations ranging from 100 ns to 10 μs. All of these properties enable us to do various experiments in materials science and technology and life sciences. The flux of radiation from storage rings as a function of photon energy can be calculated by applying classical electrodynamics to relativistic electrons on circular orbits. The falloff at high energies is determined by the characteristic energy ϵ_c (or the characteristic wavelength λ_c), which depends on the radius of curvature R, the magnetic field B, and the electron energy E. The relationship among them is as follows:

$$B(\mathrm{T})R(\mathrm{m}) = 3.34E^3(\mathrm{GeV}), \tag{1}$$

$$\begin{aligned}\epsilon_c(\mathrm{eV}) &= 2218E^2(\mathrm{GeV})/R(\mathrm{m})\\ &= 665.1B(\mathrm{T})E^2(\mathrm{GeV}),\end{aligned} \tag{2}$$

$$\lambda_c(\text{Å}) = 5.59R(\mathrm{m})/E^2(\mathrm{GeV}), \tag{3}$$

$$\lambda_c(\text{Å}) = 12\,400/\epsilon_c(\mathrm{eV}). \tag{4}$$

Furthermore, the flux of photons emitted from bending magnets at $\epsilon < \epsilon_c$ is given by

$$\begin{aligned}&I[\mathrm{photons/s\cdot mrad\cdot(0.1\%\ bandwidth)}]\\ &\quad\sim 4.5\times 10^9 R^{1/3}(\mathrm{m})\epsilon^{1/3}(\mathrm{eV})j(\mathrm{mA}),\end{aligned} \tag{5}$$

where ϵ is photon energy and j is the stored current of electrons.

The brilliance, which is another good indicator of storage rings, is defined as the number of photons per second, per 0.1% bandwidth, per unit area A of the cross section of the electron beam, and per solid angle. The horizontal and vertical beam sizes, respectively, are given by $2.35\sigma_x$ and $2.35\sigma_y$. Here σ_x and σ_y are square root of (emittance) × (β function). On the other hand, the beam divergences, σ_x' and σ_y', are almost equal to square root of (emittance)/(β function). Electrostatic and electromagnetic interactions of electrons within the beam usually increase the emittance with increasing stored current. In order to obtain a high-brilliance SR beam, the emittance ϵ_x, that is, the product of σ_x and σ_x', should be reduced.

In addition to the radiation from bending magnets, different types of radiation can be obtained from insertion devices such as wigglers and undulators, which are inserted at the straight sections of the ring. A wiggler, which is a kind of wavelength shifter, is a device in which high-energy photons are produced in low-energy storage rings because of a high magnetic field B. An undulator, which is a kind of multipole wiggler with N magnets, produces N times the photon flux of the bending magnet, because the electrons emit photons with a superposition of contributions from all points on the trajectory. The positions of interference peaks in the undulator radiation spectrum is given by

$$\lambda_m = \lambda_0/2m\gamma^2(1 + K^2/2 + \gamma^2\theta^2), \qquad (6)$$

where m is the harmonic number; λ_0 is the period length of undulator; γ is the electron-energy parameter, which is $1957E$(GeV); K is the undulator parameter, which is $93.4B$(T) λ_0; and θ is the angle at which the radiation is observed. Since the width of the undulator spectral lines is given by

$$\Delta\lambda/\lambda = 2/Nm, \qquad (7)$$

the relative spectral resolution in first order is the reciprocal of the number of periods. Thus, the first harmonic line at 100-Å wavelength with $N = 100$ is semimonochromatic with 2-Å bandwidth. While the normal undulator generates linearly polarized radiation, the helical undulator produces circular polarization, which is of great interest in the investigation of magnetic phenomena. This can be combined with electron-spin analysis.

The more advanced insertion device is a free-electron laser, which can produce a coherent laser beam with tunable wavelength by a combination of the undulator and a resonator consisting of two mirrors. The first free-electron laser experiment was performed using a linear accelerator (linac) in 1976 in the infrared region, and visible laser emission was realized in 1983. Many attempts have been carried out to produce vacuum ultraviolet (VUV) and soft x-ray laser emission using low-emittance storage rings and efficient reflection mirrors. In the near future, specific experiments using coherent x rays and extremely high-brilliance beams will become possible at the fourth-generation storage rings constructed mainly for these free-electron lasers.

By using synchrotron radiation, various kinds of advanced experiments for materials science and life science can be performed. Figure 1 shows various kinds of interactions between SR beams and materials. When the SR beam strikes the sample, various secondary emissions are generated including photoelectrons, Auger electrons, secondary electrons, fluorescence x rays, luminescence, ions desorbed from the surface, reflected x rays, elastic scattering, and inelastic scattering. In addition to these emissions, the SR beam is also absorbed in the sample, and some transmitted x rays emerge from the rear side of the sample.

By utilizing these interactions, we can obtain mainly three kinds of information. First, the atomic or crystal structure can be determined by diffraction and scattering. The structure of all kinds of materials can be analyzed with a high degree of spatial, temporal, and energy resolution. Second, the electronic state or chemical bondings can be determined by photon absorption or emission of photoelectrons and fluorescence; this

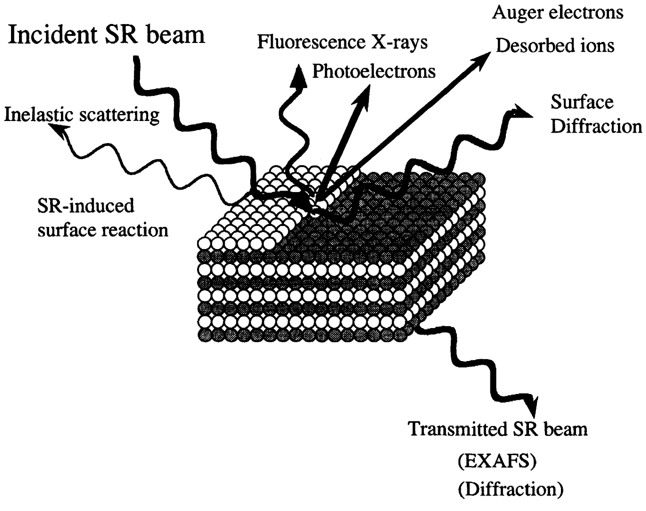

FIG. 1. Secondary emission from materials by interaction with synchrotron radiation beam.

is spectroscopy. Finally, the radiation effect can be intentionally used to change chemical bonds and atomic structure of materials, resulting in the formation of materials with different properties. One of the most important applications of this effect is x-ray lithography for ultralarge-scale integration (ULSI) devices.

2. STORAGE RINGS

The first SR beam was generated in 1947 (Edler *et al.,* 1947), and SR sources themselves have evolved, as shown in Fig. 2. The first-generation SR rings are parasitic SR sources generated in high-energy synchrotron accelerators. The second-generation rings are purpose-built dedicated SR sources with rather high emittance. The third-generation SR rings are brilliance-optimized SR sources with extremely low emittance of electron or positron orbits for insertion devices such as undulators. The fourth-generation SR rings are coherence-driven SR sources that will be suitable for free-electron lasers.

The European Synchrotron Radiation Facility (ESRF) in France, 6 GeV, Advanced Photon Source (APS) in the United States, 7 GeV, and Super Photon ring-8 (SPring-8) in Japan, 8 GeV, are outstanding SR facilities, representing the third-generation rings. These facilities can provide highly brilliant hard x-ray beams for protein crystallography, small-crystal analysis, angiography, and so on.

During the last 30 years, hundreds of SR beamlines and instruments have become available at many SR facilities in the world,

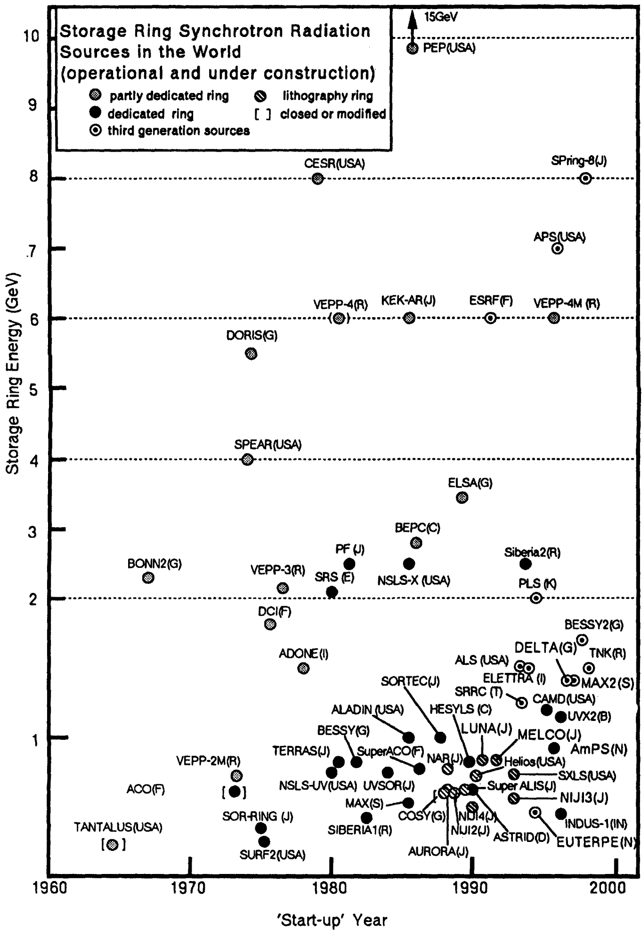

FIG. 2. The evolution of storage-ring synchrotron radiation sources over the decades, as illustrated by their increasing number and range of machine energies (Hasnain *et al.*, 1994).

and many scientists in universities and engineers in industries have recognized the usefulness of SR. At present, there seem to be two approaches in SR science and technology. One is to seek a highly brilliant SR beam as a tool for sophisticated science. This is a way to the third- and fourth-generation rings. The other is to construct more application-oriented SR rings. This is a way to the compact storage ring.

Based on the success of x-ray lithography at medium-sized SR storage rings with electron energies ranging from 2 to 3 GeV, many electronics companies have recognized the compact storage ring as an important process tool mainly for x-ray lithography for ULSI fabrication. The SR wavelength suitable for lithography, which is a kind of photochemical reaction with resist films, is about 7 Å, because photons with about 7-Å wavelength have a suitable penetration depth in resist films such as PMMA (polymethylmethacrylate). Therefore, compact storage rings of less than 800 MeV of electron energy emitting soft x rays and VUV are constructed for industrial applications. These rings are much easier than the medium SR rings from the viewpoint of radiation protection.

The first attempt at constructing a compact storage ring, named Compact Synchrotron (COSY), was made at Berlin Synchrotron Radiation (BESSY) in Germany early in the 1980s. Since there are many electronic industries engaged in dynamic random access memory (DRAM) fabrication, which requires fine patterns of less than 0.2 μm for more than 1-Gbit integration, x-ray lithography is regarded as a key technology. There are now several compact storage rings in Japan, such as Super-ALIS and NAR (NTT), LUNA (Ishikawajima-Harima Heavy Industry), AURORA (Sumitomo Heavy Industry), NIJI-2,3,4 (Sumitomo Electric Co.), Mitsubishi SOR ring (Mitsubishi Electric Co.), SORTEC, and TERAS (Electrotechnical Laboratory, Ministry of International Trade and Industry) (Ohta *et al.*, 1994). Thus, Japan has been dubbed "Synchrotron radiation island." In England, Oxford Instruments made two rings with superconducting magnets (Helios-1 and -2).

Figure 3 shows a photograph of the NTT SOR superconducting storage ring, Super-ALIS, which has ten beamline ports (Hosokawa *et al.*, 1989). The electron energy is 600 MeV with a magnetic field of 3 T, and the stored current reaches about 1.2 A. This ring is mainly utilized for x-ray lithography for ULSI fabrication.

3. MICROFABRICATION TECHNIQUES

3.1 ULSI Fabrication Utilizing Photochemical Reactions

Electronic devices such as Si ULSIs have been developed with an amazing speed following the scale-down rule. Currently 64-

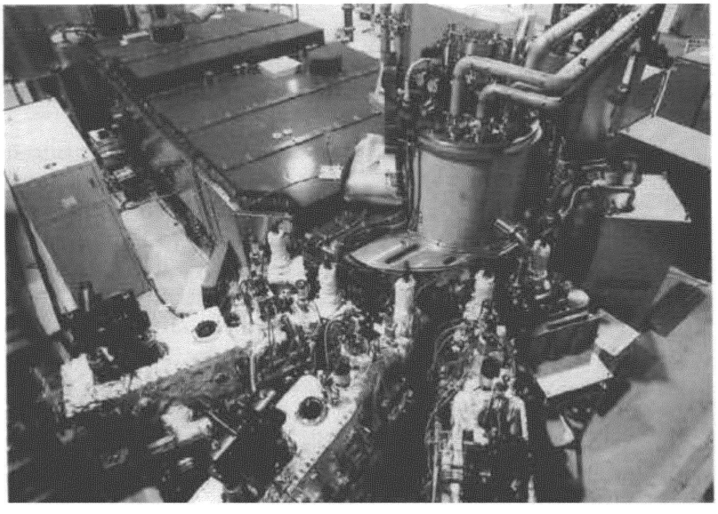

FIG. 3. Photograph of the NTT superconducting storage ring, Super-ALIS.

Mbit DRAMs are being fabricated, and the integration scale is quadrupling every three years, so that 1-Gbit DRAMs should reach commercial production in 1999 (Hayashi, 1994). In order to maintain this speed of development, process technologies providing smaller lateral scale, atomic-scale vertical abruptness, and well-controlled impurity doping are strongly required. For optoelectronic devices, more efficient light-emitting and -detecting devices are required. Figure 4 shows the trend of advanced electronic devices heading toward electron-wave devices. These devices will utilize the quantum size effect, which is being studied in the laboratory in quantum wire or dot lasers and resonant tunneling hot-electron transistors, which require atomically controlled thin-film technology together with an ultrafine lateral pattern delineation process.

In order to improve ULSI performance, there is a strong need to reduce the feature size of circuit patterns. Although various attempts to overcome the limit of optical lithography have been performed, including reducing the wavelength (by using KrF and ArF excimer lasers), increasing the numerical apertures (NA) of projection lenses (NA > 0.6), modifying illumination techniques, and using phase-shift masks, optical lithography is reaching its resolution limit, which is mostly determined by the wavelength and the focusing depth of the light.

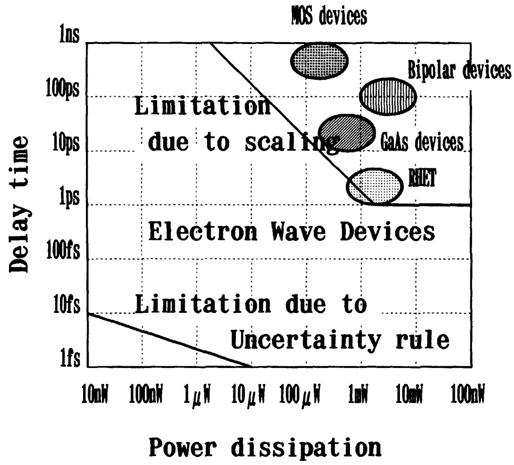

FIG. 4. Trend of advanced electronic devices plotted on a power-dissipation axis and a delay-time axis.

The first proposal for the use of x rays for lithography using a simple 1:1 proximity printing technology was made in 1972 (Spears and Smith, 1972). The x-ray mask was made of a thin membrane transparent to x rays, on which mask patterns were formed with a heavy metal that absorbs x rays. As the transmitted x rays expose the resist, the mask patterns are projected onto the wafer. When the resist films are irradiated by x rays, the chemical bonds are broken, resulting in smaller molecules that are soluble in a developing solution. This is the case for positive-type resist films. In negative-type resist films, on the other hand, x-ray irradiation makes bridges among small molecules, resulting in the formation of fine patterns that are insoluble in a developing solution. Since x-ray lithography uses a much shorter wavelength than that used in optical lithography, the resolution degrading factors such as light diffraction and interference are greatly reduced relative to optical lithography, resulting in a deeper depth of focus and a higher resolution. The resist patterns with high aspect ratio are used as etching masks for the subsequent reactive-ion etching processes to fabricate ULSI components.

Figure 5 shows a schematic view of the SR lithography system at the Super-ALIS beamline in NTT (Ishihara, 1994). In this system, the SR beam is collimated and converted to a parallel beam by two curved mirrors. To maintain the UHV in the SR ring, there is a thin Be window between the beamline and the SR stepper, which is placed in a He atmosphere. For SR lithography, a vertical stepper is used. X-ray masks consist of a finely patterned x-ray absorber film, a thin membrane film (SiN or SiC), and a Si substrate for supporting the patterned film.

Figure 6 shows a scanning electron micrograph of a 0.2-μm line-and-space resist pattern delineated by SR lithography (Deguchi *et al.*, 1992). Among nearly 30 lithography steps in the ULSI fabrication processes, more than ten steps are performed by SR lithography, while the others are done by conventional optical lithography. However, there are several difficulties in proximity x-ray lithography with one-to-one projection, such as the fabrication of x-ray masks and the axis alignment between Si wafers and x-ray masks with patterns smaller than 0.18 μm

for more than 1-Gbit dynamic random access memory (DRAM); refer to the article MICROLITHOGRAPHY.

In order to solve these problems from a different viewpoint, a unique lithography system has been developed. Figure 7 shows a schematic illustration of the two-mirror system for reduction projection lithography taking advantage of the comparably high reflectivities of multilayer-coated spherical or nonspherical mirrors in the VUV region at about 100 eV of photon energy (Kinoshita *et al.*, 1989). Using this kind of projection reduction system, fine patterns of less than 0.1 μm have been successfully delineated (Jewell *et al.*, 1990). Although this system has superior characteristics to the proximity lithography, there are still many problems to be solved, such as the small exposure area at a time, and the low reflectivity of multilayer mirrors in the soft x-ray region at several angstroms, resulting in low throughput.

3.2 Micromachine Fabrication for Micromechanics

One of the new keywords for advanced technologies is "micromachines." Many national and corporate projects have devoted a

lot of effort to fabricate micromachines equipped with microactuators, microsensors, and microprocessors. Sizes at present are a few hundred micrometers.

There are two ways to fabricate these micromachines. One is microprocessing utilizing conventional optical lithography, ion-beam etching or plasma etching for anisotropic or isotropic etching, and CVD film growth techniques, which are well-established for LSI. Many microparts such as microvalves and microactuators have been successfully made this way.

The other approach is the "LIGA" process, which is a German acronym for the three basic processes of deep lithography, electroforming, and plastic molding. This technique was developed at the Karlsruhe Nuclear Research Center (KfK) in Germany to produce very small slotted nozzles for uranium isotope separation. Figure 8 shows a schematic diagram of the LIGA process (Menz *et al.*, 1991). The base material is a layer of plastics, less than 1 mm thick, which is sensitive to x rays. PMMA is used as an x-ray resist, and a mask pattern is transferred to the

thick resist layer by an x-ray SR beam with a short wavelength of less than 0.2 nm. In SR-irradiated areas, the chemical stability of long molecular chains is changed, and they are removed in a developing solution. This is the same procedure as in the SR lithography for ULSI, except that the wavelength is short enough for deep lithography for thick resist films.

Electrodeposition on a microscopic scale is used to make a complementary structure in metals such as Cu and Ni. The metal pattern is then used to manufacture a number of plastic copies by injection molding. These plastic structures can then be filled up again with metal by a second electrodeposition process. Ceramic microstructures can also be produced. So far this LIGA technique has made various microparts including optical waveguides, microspectrometers, microturbines, acceleration sensors, and micromotors. Figure 9 shows an electrostatic motor fabricated by LIGA. The rotor is 500 μm in diameter and 100 μm high. In order to make the micromotor rotate, the underlying layer should be etched away by using a sacrificial layer that can be dissolved in an etching solution. When 65 V was applied to the stator, that is, an electrode, the rotor started to rotate along the central axis, overcoming the static friction and reaching a rotating speed of 80 rps at about 200 V. This kind of micromachining technique using SR will be extensively applied for micromachine fabrication, which will also open new possibilities in engineering, biology, medical applications, chemistry, and physics; see SYSTEMS TECHNOLOGY, MICROMECHANICAL.

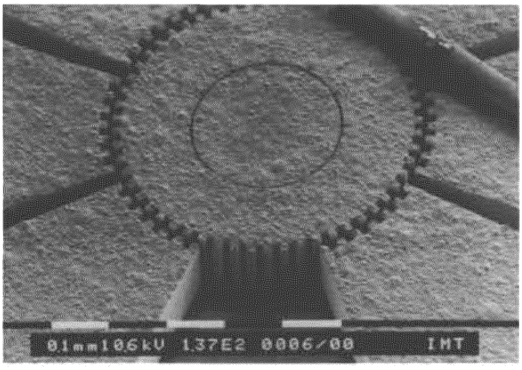

FIG. 9. Electrostatic micromotor fabricated by the LIGA process (courtesy of W. Menz).

4. SR-EXCITED PHOTOCHEMISTRY FOR PROCESS TECHNOLOGY

SR can also be utilized for surface excitation and gas decomposition for film growth of aluminum electrodes and epitaxial silicon for ULSI, and dry etching of silicon-related compound films. The merit of SR over other techniques such as thermal CVD and plasma CVD is that it enables fully selective film growth and much lower-temperature epitaxial growth, which are of importance in forming abrupt interfaces and controlling the impurity doping for fabricating advanced electronic and optoelectronic devices such as quantum-effect devices.

Figure 10 shows a cross-sectional transmission electron microscope (TEM) image of an SR-excited epitaxial Si film grown with a mixture of Si_2H_6 and H_2 at 100 °C after removal of native oxides on Si substrates (Nara *et al.*, 1992). Formation of epitaxial Si films with good quality at such a low temperature suggests the possibility of strongly suppressing interdiffusion at the interface, which is required to make abrupt interfaces on an atomic-layer scale.

The second important application is fully selective film growth, which may drastically reduce the number of fabrication process steps because of its directly patterned film growth. Figure 11 shows a schematic diagram for SR-excited–patterning aluminum CVD processes and patterned Al (Uesugi and

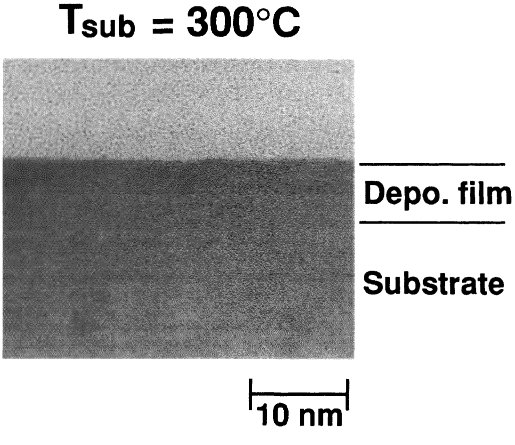

FIG. 10. TEM image of a SR-excited epitaxial Si film grown with a mixture of Si_2H_6 + H_2 at 300 °C after removal of Si native oxide at 300 °C.

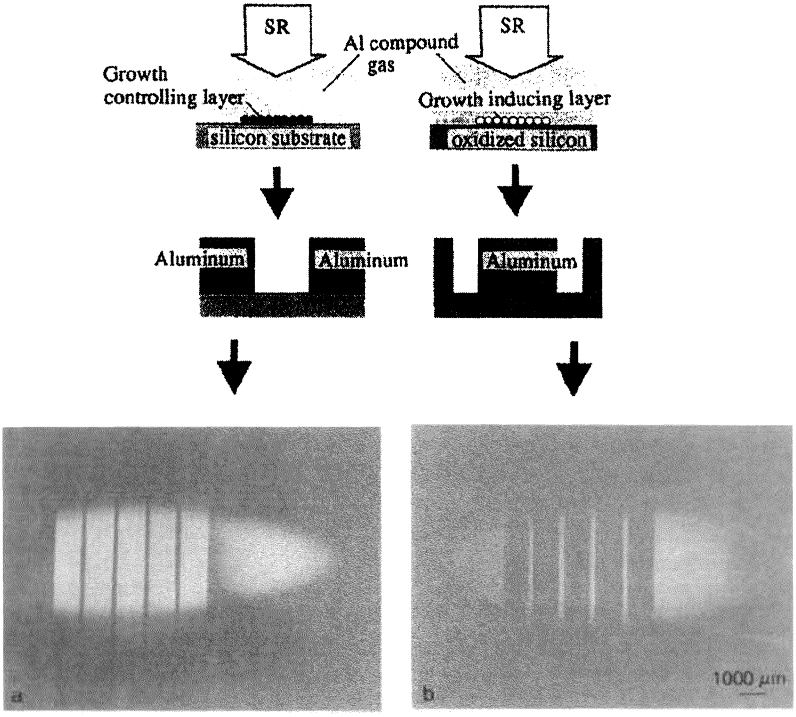

FIG. 11. Normal and inverse-projection patterning aluminum CVD by SR-induced surface photomodification.

Nishiyama, 1992). This is a kind of SR-induced surface photomodification. When SR is directed onto a Si surface that is exposed to a dimethyl-aluminum hydride (DMAH) gas, the Al compound gas containing carbon is decomposed, and an AlC-like growth-controlling layer is formed on Si, resulting in no further Al film growth. Therefore, this is called SR-excited patterning. In contrast, since such a carbide film is not formed on a Si oxide, the Al pattern is directly formed only on the SR-irradiated region of Si oxide preferentially. Thus, selective Al electrode formation is achieved with the SR-excited CVD. This leads to positive and negative direct-patterning processes by controlling the substrate surface properties.

Similar process technology was developed to grow Si epitaxial films on a Si substrate completely selectively with SR-excited CVD (Utsumi *et al.*, 1993). Here SR is directed onto a wide area where a SiO_2 film covers the Si substrate with finely patterned windows. This technique takes advantage of the property that the SR-decomposed Si_2H_6 gas fraction does not adsorb on the SiO_2 surface at all, and the epitaxial Si layer grows only on the patterned window region where the clean Si surface is exposed to the gas fraction.

The third application is atomically controlled film growth, or atomic-layer epitaxy (ALE). In the case of GaAs, the ALE is achieved only by a thermal process because adsorbed $Ga\text{-}CH_3$ fragments reject the subsequent TMG molecule adsorption. However, it was impossible to grow Si epitaxially in the ALE mode by conventional thermal CVD. Recently, ALE-mode Si growth on Ge(100) resulting from surface photochemical reaction was realized using alternating disilane (Si_2H_6) exposure and SR irradiation at a low substrate temperature of 350 °C (Akazawa *et al.*, 1993). The ALE process consists of

1. adsorption of Si_2H_6 on Ge for about 20 s from a pulse nozzle,
2. pumping the residual gas, and
3. SR irradiation for desorbing hydrogen atoms from the surface for about 200 s.

Although complete ALE growth was not achieved, this kind of surface reaction utilizing SR photochemical reaction will be useful in practice.

The mechanism of SR-excited CVD is believed to be as follows: First, SR excites core electrons in Si 2*p* or Al 2*p* core levels in Si_2H_6 or $Al(CH_3)_2H$ gases. Then, through the Auger de-excitation process such as Si_{LVV} or Al_{LVV}, two holes are created in the Si or Al valence band. Then Si–Si bonds or Al–C bonds are broken by repulsion force between Si^+–Si^+ or Al^+–C^+. Thus SR can effectively decompose metal compound gas. However, more precise analysis such as time-of-flight (TOF) analysis of desorbed ions or neutrals in terms of mass, angle distribution, and kinetic energy by changing photon energy will be needed to understand fully the SR photochemical processes.

Besides these CVD processes, the usefulness of SR etching has been also shown for Si, SiO_2, SiN, SiC, Ta, Ti, W, WO_3, TiO_2, GaAs, and diamond. Thus unique surface reactions that have been impossible by thermal process are possible through SR photochemical processes.

5. MATERIALS SCIENCE AND TECHNOLOGY

5.1 Atomic and Molecular Spectroscopy

Since the mass of the photon is zero, excitation due to momentum transfer does not happen in photon-induced excitation processes. Thus, the SR, having wavelength tunability, is an ideal probe to resonantly excite target atoms and molecules. Furthermore, the polarization property is very useful for analyzing dynamics of photoexcitation and photoionization. Various kinds of knowledge on photoninduced elemental processes of atoms and molecules are important for applications such as photo CVD, photochemical reaction, plasma physics, astrophysics, and the development of lasers.

The measurement system of atomic and molecular spectroscopy is rather simple. A monochromatic SR beam is directed onto a gaseous sample, and photoabsorption, photoelectrons, and photoejected ions are measured as a function of photon energy. For these experiments, noble gases and evaporated metal atoms are mainly used to investigate electron–electron correlation, which is one of the most important subjects in atomic physics.

The pioneering works on atomic and molecular spectroscopy using SR were done by Madden and Codling (1963) on observation of two-electron excitation in He atoms, and by Ederer (1964) on measurement of the 4*d* → ϵf giant resonance in Xe atoms.

The second important discovery was the 4*d* giant resonance of Ba, Ba^{+1}, and Ba^{+2} measured by the double-laser technique (Lucatorto *et al.*, 1981), showing that the shape of the 4*d* giant resonance strongly depends on the number of 6*s* electrons in the outermost shell. This kind of experiment is expected to extend the research field vastly to understand the phenomenon, which includes not only simple atoms and molecules in the ground states, but also ionized and excited atoms and molecules (Koizumi *et al.*, 1995). A new insight on electron–electron correlation will be obtained. However, more sensitive detectors together with much brighter SR beams are needed for ions, which have a very low density such as 10^7 ions/cm^3 because of space-charge limitation.

The third example is the measurement of the photoabsorption cross section of CO molecules. Stark *et al.* (1992) systematically measured photoabsorption cross sections of CO under the condition that the CO rotation temperature was frozen, by ejecting CO molecules from a supersonic molecular beam source to a vacuum chamber. In order to enable the precise measurement of density of CO molecules in space from the Hubble space telescope and so on, the SR photoabsorption measurement in a circumstance similar to space is necessary.

The fourth example is a new spectroscopy for inner-shell–excited molecules. Yagishita *et al.* (1989) developed a new method for the soft x-ray molecular spectroscopy of gaseous molecules by separating symmetry of inner-shell–excited states. When the photon energy is set at the $\sigma \rightarrow \sigma^*$ resonance, only the molecules that are oriented parallel to the SR electric vector are strongly excited, and the dissociated ions are emitted toward the molecular axis. Thus, the measurement of dissociated ions at $\theta = 0°$ extracts only the $\sigma \rightarrow \sigma^*$ transition, and that at $\theta = 90°$ extracts only the $\sigma \rightarrow \pi^*$ transition, as shown in Fig. 12. This "symmetry separation spectroscopy" can easily separate Rydberg states located in

FIG. 12. Principle of excitation processes for $\sigma \rightarrow \pi^*$ resonance and $\sigma \rightarrow \sigma^*$ resonance. The electric vector of the incident SR beam is in the *x-z* plane. In the case of $\sigma \rightarrow \pi^*$ resonant absorption, the molecules that are aligned perpendicular to the electric vector are strongly excited, while those parallel to the electric vector are strongly excited in the $\sigma \rightarrow \sigma^*$ resonant absorption. (Yagishita *et al.*, 1989.)

many excited states and completely discriminate the σ symmetry from the π symmetry.

Furthermore, they succeeded in measuring angular distributions of photoelectrons from molecules by using a photoelectron-photodissociated ion coincidence technique (Shigemasa *et al.*, 1995). For molecule-adsorbed surfaces, the polarization vector of SR is very useful to determine the bonding direction of adsorbates. However, since gaseous molecules are rotating in all directions, only an averaged picture of the emitted photoelectron angular distribution can be obtained. If it is possible to detect photoelectrons of molecules by an angle-resolved analyzer only when dissociated ions are detected along the direction parallel to the SR electric vector, the precise angular distribution of the emitted photoelectrons can be obtained. They measured the angular distribution of N 1*s* photoelectrons from N_2 molecules at the photon energy of 419 eV, which corresponds to the shape resonance of N_2 molecules. They found that the photoelectron distribution in the parallel condition corresponds to the $f\sigma$ component, while that in the vertical condition corresponds to the $d\pi$ component.

Thus, fundamental understandings of atomic and molecular physics in noble gases are steadily proceeding, taking advantage of the linear polarization, wavelength tunability, and high photon flux of the SR beam together with a new coincidence measurement system. With further improvement of SR beam brilliance and new detectors, atomic and molecular physics in more complicated gases will be understood.

5.2 Photoelectron Spectroscopy of Solids

Photoelectron spectroscopy (PES) is one of the most widely used surface-analysis techniques (see PHOTOEMISSION AND PHOTOELECTRON SPECTRA). PES can provide various types of information about surface composition, chemical bonds, electronic properties, and surface atomic structures. One of the major advantages of PES with SR is the very surface-sensitive analysis because the photon energy is tunable to obtain the shortest escape depth of photoelectrons (Lindau and Spicer, 1974). To make use of this advantage over the conventional x-ray photoelectron spectroscopy, *in situ* analysis is required. *In situ* surface analysis consists of growing epitaxial layers on substrates, transferring the specimen to the analysis chamber in UHV, and analyzing the surface.

With the use of high–energy-resolution grazing-incidence monochromators together with a high-efficiency hemispherical electron analyzer, it became possible to discriminate surface Si atoms showing asymmetric dimers from the second-layer Si atoms and the bulk Si atoms on Si(100) 2 × 1 and *c*(4 × 2) reconstructed surfaces (Landemark *et al.*, 1992).

Various kinds of interfaces in metal/semiconductor, insulator/semiconductor, and semiconductor/semiconductor systems have been analyzed by *in situ* PES (Brillson, 1993). These PES data are compared to electrical properties such as Schottky-barrier heights (SBHs) of metal-semiconductor contacts. The dominant works by SR-PES have been done in metal deposition on clean Si and GaAs that were cleaved in vacuum for understanding Schottky-barrier formation and controlling SBHs.

For insulator-semiconductor interfaces, oxidation processes have been widely analyzed. Initial stages of oxidation of silicon substrates have been investigated vigorously with SR-PES because the initial oxidation features are technologically important for fabricating very thin gate oxides of less than 50 Å for ULSI. Figure 13 shows Si 2*p* photoelectron spectra taken from Si(100) and (111) surfaces with 5-Å SiO_2 (Himpsel *et al.*, 1988). The experimental results that the Si(111) surface has larger Si^+ and Si^{3+} components than the Si(100) surface, which has a larger Si^{2+} component in return, are explained by the Si(111) surface structure having one dangling bond and three dangling bonds, while Si(100) has two dangling bonds.

Various SiO_2 thin films grown by different dry and wet processes using HNO_3, H_2SO_4, H_2O_2, HCl, and other solutions have been analyzed by high-resolution PES to correlate the interfacial chemical bonds with the electrical properties. Although it is well known that the SiO_2 film passivates the Si surface dangling bonds, there are high-density surface states at the oxide/GaAs interface, which strongly hinder the fabrication of GaAs MISFETs (metal-insulator-semiconductor field-effect transistors) with good quality. SR-PES analysis revealed that there exist elemental As atoms at the interface, playing a role of mobile charge or surface states (Pianetta *et al.*, 1978).

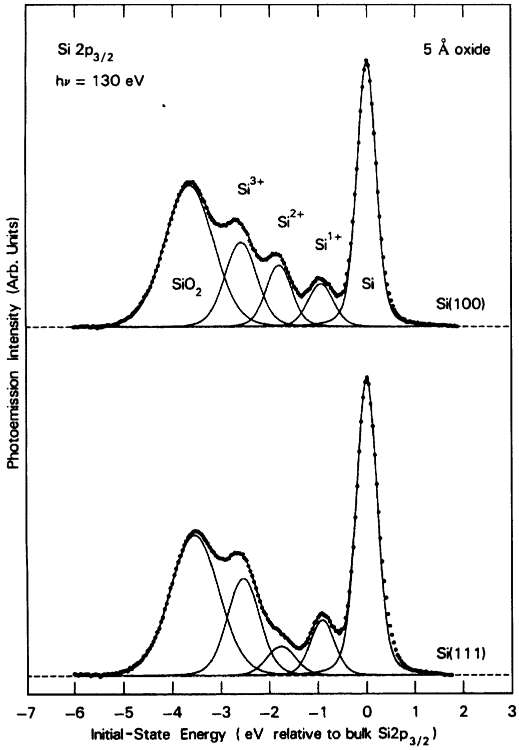

FIG. 13. Photoelectron spectra of very thin silicon oxide films on Si(100) and (111) surfaces measured with high-energy resolution.

CaF_2 is a promising candidate for an epitaxial insulator film grown on a GaAs substrate with a low interfacial state density. The analysis of interfacial chemical states by SR-PES and surface morphology by RHEED revealed that when CaF_2 is grown on GaAs(111)*B*, a layer-by-layer growth with an abrupt interface is obtained, while CaF_2 on GaAs(100) has decomposed Ca^0 at the interface (Yamada *et al.*, 1988). On the basis of these SR-PES results, for MIS diode applications, a perfectly lattice-matched $(Ca_xSr_{1-x})F_2$ epitaxial insulator was grown on GaAs(111)*B*, which showed a very low interface state density of $1 \times 10^{11}\ \mathrm{cm}^{-2}\ \mathrm{eV}^{-1}$ (Waho and Seki, 1991). This is a good example for the usefulness of *in situ* SR-PES for device applications.

With the drastically improved energy resolution in PES, various types of information about surface and bulk properties can be obtained in addition to chemical components and bondings. Photoelectrons contain chemical and electronic information about solids. By analyzing photoelectrons with a high–angular-resolution analyzer, band structure can be obtained. One example is the direct determination of the superconducting gap energy of high-T_c oxide superconductors. Using extremely high–energy-resolution angle-resolved PES, the gap energy was determined to be 24 meV for a $Bi_2Sr_2CaCu_2O_8$ sample using a 22-meV energy-resolution setup (Olson *et al.*, 1989). This result supports the Fermi-liquid model for the superconducting mechanism. The other example of high–energy-resolution PES is the direct observation of the quantum size effect of nanocrystals. Quantum confinement energy was determined to be several tens of meV for 24-Å CdS nanocrystals (Colvin *et al.*, 1991). In the angle-resolved PES, photoelectrons are analyzed in terms of their emission (azimuthal and polar) angle and their kinetic energies. The kinetic energy gives the binding energy as the energy difference from the Fermi energy. The internal wave vector of the photoelectrons must also be determined to test the calculated electron-energy dispersion. Figure 14 shows angle-resolved photoelectron spectra measured from a cleaved GaAs(110) surface, from which band mapping showing good agreement with the pseudopotential theory is achieved (Chiang *et al.*, 1979). This technique has been applied to epitaxial GaAs(100) layers, HF-treated Si surfaces, alkali-metal–deposited Si surfaces, and so on.

Besides these chemical and electronic state analyses, the photoelectron diffraction technique, which is a kind of angle-resolved PES, can give unique information about surface structures of adsorbates or the surface itself. By using a two-dimensional electron analyzer (Daimon, 1988), a 180° distribution of photoelectrons can be displayed on the screen. This photoelectron diffraction pattern can be regarded as a hologram in *k* space. Therefore, by analyzing the hologram by computational Fourier transformation, a photoelectron holograph in real space can be obtained (Barton, 1988). Figure 15 shows three photoelectron diffraction patterns of Si 2*p* obtained from a Si(111) 7 × 7 reconstructed surface by using incident SR beams of different energies, and a Fourier-transformed photoelectron holographic image (Daimon, 1993). The cross points correspond to the neighboring Si atom positions.

Furthermore, the microanalysis of surfaces and interfaces became possible, taking advantage of the low divergence of SR. A very small SR beam spot of about 0.1 μm has been achieved for microphotoelectron spectroscopy (Williams *et al.*, 1995). Figure 16 shows a schematic diagram of a micro-beam PES system with an undulator, a monochromator, a Schwarzschild objective lens, and a sample scanning stage for two-dimensional imaging (Ng *et al.*, 1990). Two-dimensional compositional and chemical-state

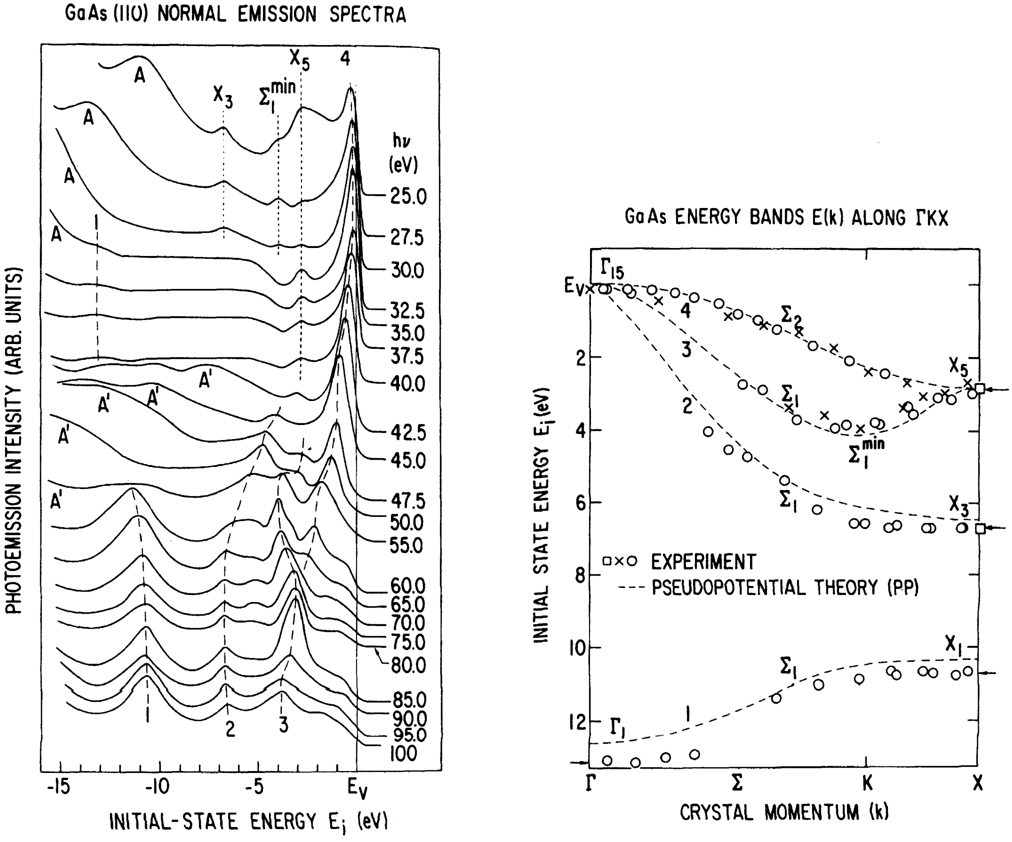

FIG. 14. Angle-resolved photoelectron spectra taken from a cleaved GaAs(110) surface and the derived band structure.

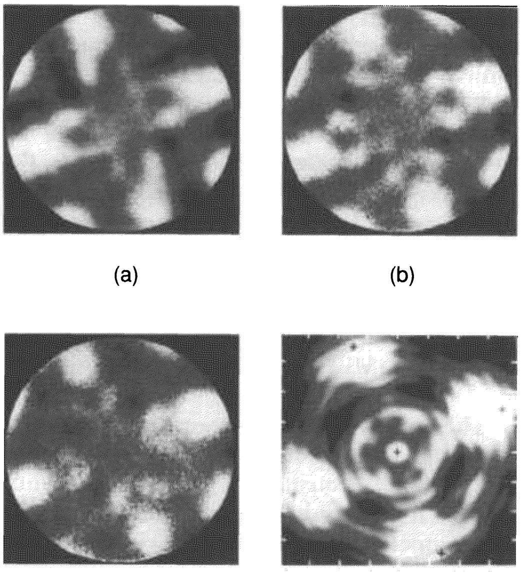

(a) (b) (c) (d)

FIG. 15. (a)–(c) Si 2*p* photoelectron diffraction patterns obtained at the photoelectron kinetic energies of 350, 400, and 650 eV, respectively, by using a two-dimensional photoelectron analyzer. (d) Photoelectron holography of Si(100) surface calculated from (a)–(d).

mapping was achieved, which should be useful for in-process diagnosis of microdevices during fabrication processes.

In the near future, SR-PES will be further improved by higher resolutions in energy (several meV), in lateral dimension (several tens of nanometers), in angle (less than 1 degree), and in time (several milliseconds). Third-generation SR sources with high brilliance will be required in order to realize these high-resolution PESs.

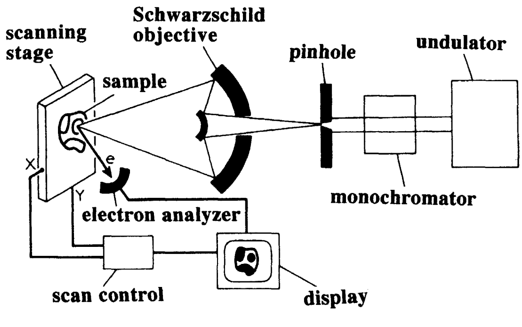

FIG. 16. Schematic diagram of a photoelectron microscope using a SR microbeam from an undulator source.

5.3 Extended X-Ray Absorption Fine Structure (EXAFS) and X-Ray Absorption Near-Edge Structure (XANES)

The EXAFS technique (Teo and Joy, 1986) provides information about the atomic structure in the immediate vicinity of an x-ray–absorbing atom. The photoelectron emitted after absorption can be regarded as a wave. This wave interacts with the atoms surrounding the absorbing atom, resulting in a modulation of the absorption spectrum at energies higher than the absorption edge. Deconvolution of these modulations provides information about the number, types, and distances of neighbors. Therefore, EXAFS is complementary to diffraction, which naturally reflects the translation symmetry of the material. Thus, EXAFS can be applied to materials of any phase, crystalline and noncrystalline solids, solutions, or gases.

One of the classes of materials most widely analyzed by EXAFS is catalysts. It is well known that catalytic effects strongly depend on the structure of the catalyst. For dispersed metal catalysts consisting of small metal clusters dispersed on the surface of silica or alumina (carrier), the interaction of oxygen with 1% Ru on a silica catalyst was studied *in situ,* and it was found that bulk oxidation occurred and destroyed the Ru lattice (Lytle *et al.,* 1977). Other catalysts such as metal oxide catalysts and homogeneous catalysts were also successfully analyzed by EXAFS, where reactions such as polymerization and hydrogenation processes were well correlated with structure changes. Such knowledge will increase our understanding of catalytic reactions, leading to significant improvements in catalysts.

Metal cluster particles in colloidal dispersions as well as small metal particles in supported catalysts were analyzed by EXAFS to determine the local structure. As an example for the characterization of the exact structure of the bimetallic clusters in supported metal catalysts, Sinfelt (1987) characterized Ir/Rh, Au/Cu, Ru/Cu, and Os/Cu bimetallic clusters supported on silica by means of EXAFS and found that the surface can consist entirely of Cu in the form of a monolayer and that the core consists of ruthenium.

With the increased x-ray flux available from a SR source, the range of target materials is expanding from the conventional bulk materials to targets containing many fewer atoms. One of the important materials in semiconductor devices is impurity atoms implanted into Si substrates. The local geometry or environment of impurities incorporated in Si substrates by ion implantation was analyzed by EXAFS. Figure 17 shows EXAFS spectra for the As-implanted Si(100) substrate with a dose of 3 × 10^{16} cm^{-2} at 100 keV followed by laser annealing. The Si substrate was then annealed at 350 °C and higher temperatures. It is found that the subsequent annealing changed the As–Si distance from 2.41 to 2.37 Å and the coordination number from 4 to about 3. From these results, a model was developed based on As-rich vacancy complexes such as As_4V at 350 °C and SiAs precipitates at higher temperature. The structure information was well associated with the marked decrease in the carrier concentration in Si during the annealing process (Allain *et al.*, 1993).

Surfaces and interfaces are also important targets of EXAFS where the number of target atoms is quite small compared to bulk atoms. The structure of Ge epitaxial overlayers on Si(001) has been studied by the *in situ* surface-sensitive EXAFS technique after growth by MBE. The oscillatory intensities of RHEED during the growth of Ge overlayers were utilized to control the number of Ge layers. The Ge EXAFS spectra for Ge overlayers on Si(001) have been obtained by detecting the Ge fluorescence signal in a total-reflection geometry where only the subsurface (50 Å) region is probed. Fourier-transform analysis of EXAFS oscillations revealed the expanded dimer structure of 1 monolayer (ML) Ge on Si(001) (Oyanagi *et al.*, 1994).

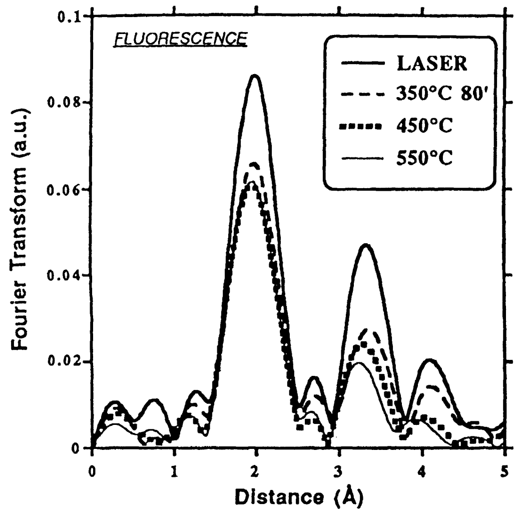

FIG. 17. EXAFS analysis of As-implanted and laser-annealed Si substrates.

The strained Ge–Si system is expected to be useful for optoelectronic devices because of its direct transition-type band structure and for high-speed electronic devices such as heterojunction bipolar transistors. By analyzing a 340-Å pseudomorphic Ge–Si film by EXAFS and x-ray diffraction for the short-range order and the long-range order, respectively, the Ge–Ge and Ge–Si first-neighbor bond lengths of 2.44 and 2.38 Å were found to coexist. Furthermore, the pseudomorphic epitaxy produces an expansion of the Ge_xSi_{1-x} lattice spacing perpendicular to the interface and a contraction parallel to the interface (Woicik *et al.*, 1991). This kind of interface analysis was also conducted for InGaAs/GaAs multiquantum wells, ZnSe/CdSe superlattices, SiO_2/GaSe/GaAs MIS structures, lattice-matched InGaAs/InP quantum-well heterostructures, and Si/GaAs interfaces.

Initial oxidation features of GaAs surfaces were analyzed by surface EXAFS utilizing secondary electrons (Stohr *et al.*, 1979). From the analysis of GaAs oxide of 1 monolayer (ML), which was formed by exposure to 5 × 10^9 Langmuir (1 Langmuir = 10^{-6} Torr-s) of oxygen, the As–O distance was determined. Furthermore, the O–As and O–Ga distances on the plasma-oxidized GaAs surface were determined for MIS device application (Oshima *et al.*, 1988). In order to analyze surface and interface structures, a gas-scintillation proportional counter (GSPC) was developed for effectively detecting soft x rays from light elements such as oxygen and carbon (Maeyama *et al.*, 1991). This detector was also applied to structure analysis of the surface sulfur layer, which is reported to play an important role of atomic-layer passivation for GaAs MESFETs. This passivation was performed by etching the GaAs substrate with an $(NH_4)_2S_x$ solution and annealing in vacuum, resulting in 1–2 monolayers of Ga–S bonds. An x-ray standing-wave (XSW) study of this system also determined the Ga–S atomic distance to be 2.30 Å, assuming no surface relaxation. Since the Ga–S distance determined by surface EXAFS was also 2.31 Å, it can be concluded that there is almost no surface relaxation caused by sulfur passivation (Maeyama *et al.*, 1995).

More spatially resolved information can be obtained by microbeam EXAFS. Using a Kirkpatrick–Baez mirror configuration as an x-ray focusing element, the x-ray beam size on the sample was reduced to around 5 μm with a photon flux of 10^7–10^8 photons/(s 300 mA) (Iida *et al.*, 1993). With the use of a highly brilliant SR beam from the third-generation rings, the microbeam EXAFS will be extensively applied to various electronic, chemical, and biological materials.

Finally, a unique application of x-ray absorption spectroscopy is reviewed—that is, the element-specific magnetic microscopy with circularly polarized x rays. The magnetic contrast arises from the fact that the x-ray absorption cross section at inner-shell absorption edges of aligned magnetic atoms depends on the relative orientation of the photon spin and the local magnetization direction. It is reported that magnetic imaging of a CoPtCr magnetic recording disk with a lateral resolution of 1 μm was obtained using the magnetic circular X-ray dichroism (MCXD) technique (Stohr *et al.*, 1993). The monochromatic soft x rays were incident at an angle of 30° from the surface, and the secondary electrons were accelerated into the microscope along the surface normal. Secondary electrons of about 6-eV kinetic energy were focused into an image using a two-stage electrostatic lens system. The pattern obtained at the photon energy of 778 eV, that is, the Co L_3 edge, shows the same image as the pattern at 793 eV, that is, the Co L_2 edge, but with reversed contrast. Thus, the magnetic contrast results from the alignment between photon spin and magnetization vectors. The feasibility of magnetic microscopy by using undulator insertion devices (factor of 100 in flux) and x-ray focusing optics (factor of 100 in spot size) was estimated, resulting in 100×100-Å^2 MCXD microscopy. This kind of magnetic microscopy with different photon energies may enable element specificity, chemical-state specificity, and variable probing depth. Furthermore, by combining the MCXD microscopy with NEXAFS and EXAFS, one can obtain magnetic, chemical, and even structural information on the same microscopic area.

5.4 X-Ray Standing Waves

While scanning tunneling microscopy (STM) is a useful tool for obtaining detailed information about the lateral distribution of surface atoms with atomic-scale resolution, it does not readily provide information on distances perpendicular to the surface. This kind of information can be obtained from surface EXAFS and x-ray standing waves (XSW). Therefore, these techniques are the ideal complement to STM studies. Since XSW is simpler than surface EXAFS in several ways such as simple mathematical analysis, much narrower photon energy range for energy scanning, and three-dimensional position determination (triangulation), XSW is becoming more popular for structure analysis.

When monochromatic x rays impinge onto crystals such as Si and GaAs having perfect crystallinity, the incident and the diffracted x-ray beams interfere to produce a standing wave with nodal and antinodal planes that are parallel to the diffraction plane. If the target atoms on the surface are located at the net plane, which in principle corresponds to the lattice plane as shown in Fig. 18, the electrons surrounding the atoms are strongly excited when the antinodes of the standing waves exist at the net plane, that is, condition 3 in Fig. 18, corresponding to the high-angle side of the Bragg condition. On the other hand, when the nodes exist at the net plane, that is, condition 1, the atoms are not excited at all in principle. Changing the x-ray incident angle causes the standing-wave nodes to move continuously from the diffraction plane to between the planes. By monitoring the secondary-emission yields from the target atoms, such as fluorescent x rays, Auger electrons, or photoelectrons, the position of these atoms relative to the diffraction planes can be determined. The analysis of the profile gives the exact position of the target atoms regardless of whether they

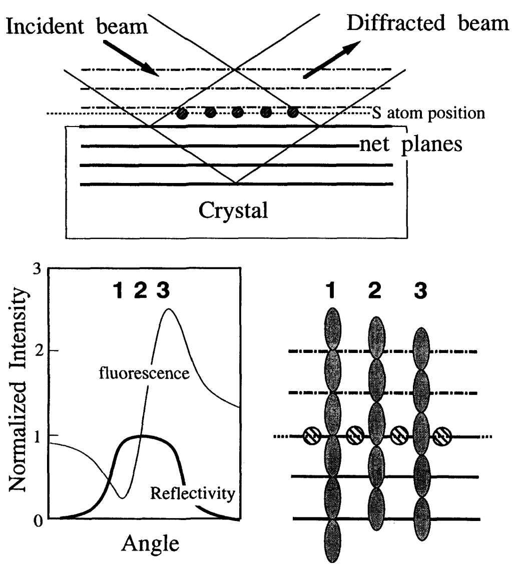

FIG. 18. Principle of x-ray standing wave (XSW) analysis.

exist at the surface, in the overlayer, or at the substituting atomic position in the crystals.

After the theoretical formulation of XSW analysis with the x-ray dynamical diffraction theory was established, XSW has been extensively applied for semiconductor surfaces and impurities such as As and Bi atoms doped into Si. In the 1980s many studies were performed using synchrotron radiation. With regard to chemisorption on Si, structure analysis was done on Br adsorbed on the cleaved Si(111) surface in UHV (Dev *et al.,* 1985). Submonolayer Ge (Patel *et al.,* 1985) and Au (Berman *et al.,* 1988) on Si(111) were also analyzed.

Heteroepitaxial overlayers such as $NiSi_2$/Si(111) (Vlieg *et al.,* 1986), CaF_2/Si(111), and GaAs/Si(111) (Kawamura *et al.,* 1991) are very important systems for device applications such as Schottky-barrier diodes, MIS devices, and solar cells. Since their electrical properties are sensitive to the interfacial structure and bonds, precise analysis of interfaces is required. XSW analysis of $NiSi_2$/Si(111) reveals that both A-type (untwinned) and B-type (twinned) $NiSi_2$ films epitaxially grown on Si(111) substrates have the same sevenfold coordinated interface, but the A type has larger inward relaxation (0.16 Å) than the B type (0.07 Å). This 0.09-Å difference in interface relaxation is thought to be responsible for the difference in Schottky-barrier heights observed for A- and B-type epitaxial films. Thus the fundamental electrical properties are reflected in interfacial structures. Furthermore, initial stages of epitaxial overgrowth such as GaAs on Si and Sb compounds on InP(110) (Kendelewicz *et al.,* 1991) were precisely investigated by XSW.

In order to fabricate GaAs MISFETs with a higher operating speed, the defect density at the interface should be drastically decreased. An epitaxial CaF_2 film with good interface chemistry was grown on sulfur-passivated GaAs (Scimeca *et al.,* 1991). In order to elucidate the sulfur passivation mechanism, the S atomic position was determined three-dimensionally by means of XSW triangulation (Sugiyama *et al.,* 1993). Plate 1 shows XSW profiles of CaF_2/S/GaAs(111)*B* and a structure model for the interfacial sulfur atoms constructed on the basis of combined photoelectron spectroscopy and XSW results (Oshima *et al.,* 1993). By analyzing the XSW profile, the S position was determined to be at the hollow site having three bonds with Ga, substituting for an As. The thermodynamically stable S–Ga bonds play a key role of drastically reducing GaAs surface defects. Thus the interfacial structure (obtained by XSW) together with the chemical bondings (obtained by SRPES) are successfully correlated with electrical properties (*I-V* or *C-V* methods) (Sugiyama *et al.,* 1992).

Furthermore, XSW is also used to determine the implanted impurity position of Bi in Si (Hertel *et al.,* 1985). Two reflection orders, (220) and (440), were used with SR to study the impurity distribution function at five doses ranging from (0.6 to 10) $\times 10^{14}$ Bi atoms/cm^2. The analysis reveals that the substitutional fraction of Bi position decreases from 100% to about 40% with increasing implantation dose, which can be related to a lattice expansion and the formation of precipitates.

A new application of the XSW was attempted (Lessmann *et al.,* 1995), in which not only Bragg reflection from the GaAs(001) substrate but also satellite diffraction from an AlAs/GaAs/AlAs/ . . . /GaAs superlattice were utilized. Photoelectrons for probing the shallow region and fluorescent x rays for probing deeper region were detected. When photons with 5.3 keV energy were incident on the short-period AlAs/GaAs superlattice (460 bilayers) on GaAs(001) substrate, a clearly modulated XSW profile of photoelectron yield was detected at the zeroth-order superlattice reflection, that is, about 55.82° of θ. The reflection can be interpreted as a Bragg reflection from the averaged unit cell of one superlattice period. Thus, the XSW method can give new insights into the structure of heteroepitaxial systems and buried interfaces.

5.5 X-Ray Diffraction: Microdiffraction, Surfaces, and High-Pressure Conditions

X-ray diffraction (XD) has been the most useful technique among hard x-ray applications such as diffraction, Compton scattering, absorption, fluorescence, nuclear resonance, and angiography. These techniques are now routinely used to characterize various crystals. By using the highly brilliant SR beam, it became possible to analyze crystals with small numbers of target atoms, such as microcrystals and surfaces (or interfaces).

A microdiffraction technique has been developed to analyze microcrystals by means of the Laue method using intense SR white x-ray beams. The performance of the extremely small Laue diffraction method was verified using a 0.8-μm-diameter Mo crystal. CVD diamond, $BaTiO_3$, $(Fe,Mg)_2SiO_4$, and interplanetary dust particles consisting of $(Fe,Ni)_{1-x}S$ with about 8-μm diameter have been analyzed. At present, it becomes possible to analyze about 2×10^{-2} μm^3 of microcrystal, which contains only 5×10^8 atoms. The crystallographic study of small crystals is expected to greatly advance protein and medical studies. Determination of crystal structures should lead directly to the development of new medicines. Recently, a glass capillary with an entrance inner diameter of 22 μm and an exit inner diameter of 3 μm was found to be very useful for obtaining a fine (less than 100 nm) beam of about 10-keV hard x rays, which will be applicable to microcrystallography and microphotoelectron microscopy (Bilderback *et al.*, 1994). Laue diffraction patterns were taken from a lysozyme crystal with a 5.6-μm-diameter x-ray beam and from a lithographically prepared gold pattern with a 360-nm beam. This is the smallest x-ray beam for protein crystallography experiments, taking advantage of the high flux of a low-divergence SR beam. This technique will be applicable to crystallographic diagnosis for finely patterned ULSI parts of submicron size.

The second application is surfaces and interfaces, where there are very few atoms compared to the bulk atoms. Because of the brilliant SR beam, sharp diffraction spots have been obtained from about 10^{14} atoms/cm^2. It is found that the superstructure that used to be believed to exist only on the clean surface in UHV also exists at the metal/semiconductor and insulator/semiconductor interfaces. Although many interface studies have been done on metal/semiconductor interfaces to control SBHs (Schottky-barrier heights) so far, atomic-level interface structures have not been elucidated yet. Akimoto *et al.* (1991) for the first time succeeded in the interface structure determination of Al/Yb/GaAs(100) systems having different reconstructions at the interface using grazing-incidence x-ray diffraction (GID). The Al/Yb/GaAs(100) with a 3-Å Yb interlayer having 0.76 eV of SBH showed a quite different atomic arrangement at the interface from that with a 32-Å Yb interlayer having 0.83 eV of SBH, although they both showed the same 4×1 superstructure. Thus, Schottky-barrier heights of these contacts are well correlated with the interfacial atomic arrangement.

Direct observation of Ge and Si ordering at the interface was performed by anomalous x-ray diffraction (Tweet *et al.*, 1992), which is a modification of GID at the Ge K absorption edge. The ordered $\sqrt{3} \times \sqrt{3}$ structure with interfacial boron atoms was analyzed for the heteroepitaxial $Ge_{1-x}Si_x$/Si(111) B($\sqrt{3} \times \sqrt{3}$)$R30°$ interface, which can be used for electronic devices with a strained-layer superlattice. By analyzing the diffracted intensities in a Patterson's map, the interfacial displacement of boron, silicon, and germanium atoms was precisely determined.

This surface diffraction technique was applied to the GaAs crystal growth process in the metallorganic chemical vapor deposition (MOCVD) process. During the crystal growth process using trimethylgallium (TMG) and tertiarybutylarsine (TBA) gases, x rays were directed onto the surface at a grazing-incidence angle to understand the growth mechanism and monitor the atomic-level layer-by-layer growth process (Kisker *et al.*, 1992). If the sample is atomically flat over the coherent length of the x rays, the surface scattering should be observed at the 110 reflection position, which is forbidden for the bulk. Thus the observation of 110 diffraction verifies the atomic layer-by-layer growth. As shown in Fig. 19, the oscillation of x-ray scattering intensity is also useful to monitor the layer-by-layer growth process in much the same fashion as RHEED oscillation in MBE growth (Fuoss *et al.*, 1994).

Under extremely high-pressure conditions, a lot of novel properties have been reported, such as insulator–metal transition and insulator–superconductor transition. Since these electrical properties are well correlated with crystal structures, it is of great importance to investigate the crystal structure change *in situ* under high pressure. So far, various kinds of materials such as graphite, BN, Mg_2SiO_4 and $MgSiO_3$, BaS, Ni_2SiO_4, Ga, Bi, Se, Te, I, Cs, S, O, Si, Ge, Sn, and III–IV compounds have been analyzed.

In the largest-volume press system, the energy-dispersive x-ray (EDX) diffraction technique with SR has been used in many studies, such as precise determination of pressure–temperature phase diagrams and equations of state. Although the EDX diffraction mode has an advantage of quick acquisition of diffraction data, it is difficult to derive reliable diffraction intensity for each reflection peak on account of uncertainty of the spectrum of incident radiation and difficulty in making precise correction of absorption effects. Thus, an angle-dispersive x-ray (ADX) diffraction measurement is necessary. A combined diffraction system with energy-dispersed XD (EDX) and angle-dispersive XD (ADX) was developed for high-pressure structure studies using a cubic-type multianvil press (Kikegawa *et al.*, 1995). Quick recording of the diffraction pattern is made in the EDX diffraction mode for pressure determination, and sample identification and high-quality diffraction patterns with reliable diffraction intensities are obtained in the ADX diffraction mode. The structure relation between Bi III and Bi III′ was investigated with this system. The volumetric compressibility was obtained by the EDX mode, and the atomic arrangement was determined from the data obtained in the ADX mode. The crystal structure of Bi III′ was found to be identical to that of Bi III.

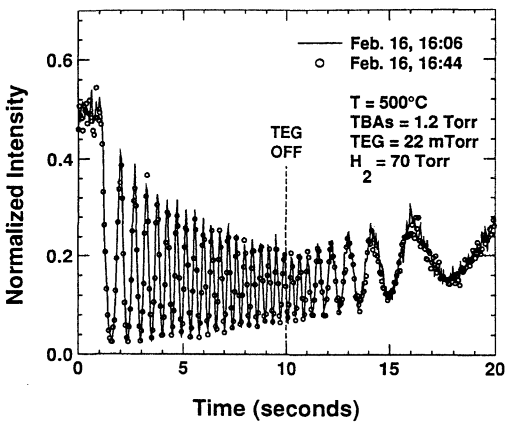

FIG. 19. Real-time monitoring of MOVPE homoepitaxial GaAs growth process by means of grazing-incidence x-ray diffraction. In the MOVPE growth, TBA (tertiarybutylarsine) gas and TEG (triethylgallium) gas were used (Fuoss *et al.*, 1994).

5.6 Topography and Tomography

As far as x-ray topography is concerned, a very bright SR beam opened two unique aspects in time-resolved analysis (real-time imaging) and high–angular-resolution analysis. X-ray topography with the very bright SR beam was applied to real-time monitoring of the GaAs and GaSb LPE (liquid-phase epitaxy) growth processes (Sato *et al.*, 1985). Real-time topography images of the solid–liquid interface taken with a Saticon image intensifier at (220) reflection revealed that a lot of slip zones are generated when the substrate temperature increases. The decrease of diffracted x-ray intensity would be entirely expected, since the positional ordering of the atoms disappears on melting.

The mechanism of primary recrystallization of steel sheets was investigated by *in situ* x-ray topography (see TOPOGRAPHY, X-RAY), which can provide rapid projection of the crystal grain orientation distribution in polycrystalline materials (Kawasaki *et al.*, 1995). The measurement system consists of an x-ray two-circle diffractometer and a translating imaging plate holder. Titanium-added ultralow carbon mild steel sheets with the thickness of 0.1 mm were used as a sample. A monochromatic SR beam of 0.06-nm wavelength was focused on the sample, which was rotated, while the imaging plate for detecting diffracted x rays two-dimensionally was translated. The results of measurements on some alloy sheets showed that the pattern recorded contains information about microstructures, size, and strain of crystal grains. Successive growing of crystal grains is seen as an increase in the size of diffraction spots. Thus, the rapid-projection method of crystal grain-orientation distribution is found very useful for investigating the primary recrystallization process of steel sheets for improving the mechanical properties of steel products.

A plane-wave topography technique with extremely high angular resolution was developed to characterize dislocation-free Si CZ (Czochralski method) and FZ (floating-zone method) wafers (Ishikawa *et al.,* 1989). The capability of producing a highly collimated x-ray beam at a desired wavelength enabled ultraplane-wave topography (UPWT) by a four-crystal arrangement. The interference pattern, which is usually smeared out in the conventional double-crystal system, can be clearly observed even for FZ Si wafers. Minute strain fields around defects are imaged on a topography as equal-inclination fringes. This technique with angle resolution of less than 0.01 arcs is also applicable to evaluation of process-induced microdefects or strains.

In addition to these two aspects in x-ray topography, a new aspect in x-ray computed tomography (CT) has appeared for nondestructive evaluation of industrial materials and medical diagnostics, after Hounsfield first developed this technique (Hounsfield, 1973). This CT becomes a more powerful tool using synchrotron radiation, because SR is an ideal x-ray source for a CT scanner since it can provide a highly collimated, high-intensity, tunable monochromatic x-ray beam. Thus the high–energy-resolution monochromatic x-ray CT (SR-CT) has enabled the imaging of element distribution and different chemical bonding states, *in situ* observation of transient phenomena, and various materials evaluation. One of the most important applications of this technique is medical diagnostics using K-edge subtraction for coronary angiography, which does not require high spatial resolution.

A new SR-CT method with the spatial resolution of about 10 μm has been developed (Hirano *et al.,* 1995). Figure 20 shows a three-dimensional CT image of a SiC/A 2024 composite rendered from 20 CT images taken at the maximum stress. The arrow *a* indicates a carbon fiber, which SiC fibers are surrounding. The arrow *b*, the transparent part, indicates the void that was formed by extraction of a fiber. The neighboring arrow *c* is also the void. Thus, the SR-CT method is

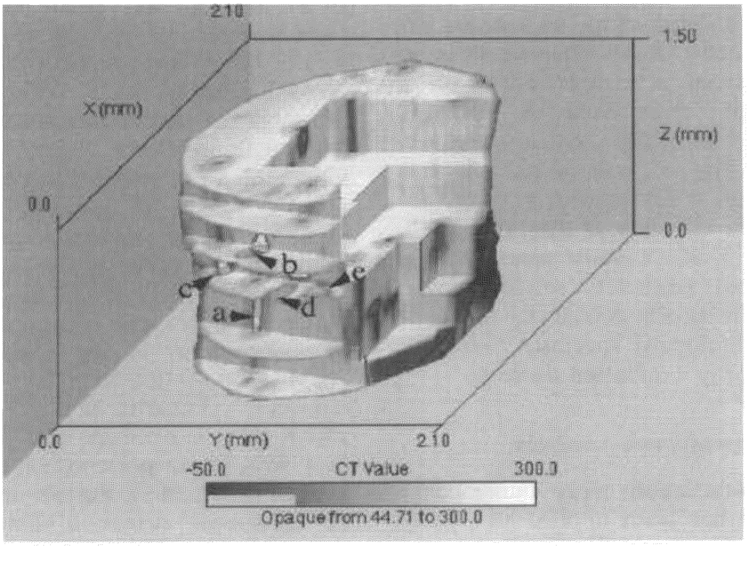

FIG. 20. A three-dimensional CT image of a SiC/A 2101 composite (Hirano *et al.*, 1995).

useful for nondestructive evaluation of materials. In order to improve the lateral resolution of SR-CT, more parallel incident x rays and submicron x-ray detectors should be developed. Furthermore, *in situ* observation of materials under heating and stress-field conditions will be important for elucidating destruction, deformation, and growth mechanisms of materials.

However, it is difficult to obtain high-contrast x-ray transmission images of organic materials using the ordinary CT method, since x-ray absorption coefficients of light elements are extremely small. In this respect, phase-contrast x-ray imaging using an x-ray interferometer is promising for observing the inner structure of organic materials. This is because even light elements cause x-ray phase shifts large enough to be detected. A phase-contrast x-ray CT (PCX-CT) using an x-ray interferometer to detect phase shifts has been developed (Momose *et al.*, 1996). The researchers used the fringe-scanning method to read the phase shift precisely from several interference patterns obtained by varying the external phase shift. Figure 21(a) shows an x-ray interferometer having three crystal plates for a phase-contrast CT image. When the incident beam to the x-ray interferometer satisfies the Bragg condition, an object beam and a reference beam are created. A liquid cell is inserted in the object-beam path. A wedge-shaped phase shifter in the reference-beam path is moved vertically to read the phase shift from interference patterns detected by an imaging detecter. Figure 21(b) shows phase-contrast x-ray CT images of a sample cut from a cancerous rabbit liver fixed in formalin. Shown in **a** is one of the reconstructed sectional images. The left half of the image is the cancer lesion. A 3D expression of the entire body of the CT data is displayed in **b**. Thus, PCX-CT is much more sensitive than the conventional x-ray CT, suggesting the possibility of drastically decreasing the x-ray dose into the biological specimen, which is vulnerable to x-ray irradiation damage.

5.7 X-Ray Fluorescence Analysis

Synchrotron-radiation x-ray fluorescence analysis (XFA) has been applied to nondestructive trace-element analysis of samples of biological, environmental, mineralogical, and industrial interest. The minimum detection limits are of the order of parts per billion. Using an SR x-ray microbeam, obtained with a Kirkpatrick–Baez mirror system (Noma and Iida, 1994), two-dimensional distributions of trace elements (elemental images) can be obtained with a lateral resolution of a few micrometers.

The x-ray microbeam technique has been applied also to surface and chemical-state analysis on a spatial scale of a few micrometers. Elemental distributions of K and Zn from the cross section of a human hair were used to demonstrate the lateral resolution (Iida and Noma, 1994). Furthermore, this technique is applicable for insulators, because XFA is free from the charging-up effect.

When x rays with good parallelism impinge onto a flat surface with a grazing angle lower than the critical angle such as 3.9 mrad for Si at the photon energy of 8 keV, total reflection occurs, resulting in a very shallow penetration depth such as 32 Å for Si. This total-reflection XFA was recognized as a useful analytical technique for trace analysis in a solution dropped onto a flat substrate surface. Since the background originating from the substrate can be drastically reduced because of the extremely shallow penetration depth, a very low detection limit such as parts per billion was obtained. This technique has been applied to surface impurity analysis on Si (Brennan *et al.*, 1994), because heavy-metal surface impurities such as Fe and Ni may create atomic-scale defects that lead to leakage currents, gate insulator breakdown, or poor threshold-voltage control, causing device reliability problems. Although the best conventional total x-ray reflection fluorescence (TXRF) using a rotating-anode x-ray source has achieved a sensitivity of 5×10^9 atoms/cm^2, the rapidly evolving ULSIs require a better detection limit, on the order of 10^8 atoms/cm^2. The combination of the bright SR beam from the 8-pole wiggler and the double-multilayer monochromator in the TXRF arrangement enabled a detection limit for Ni of 2.5×10^8 atoms/cm^2 (Pianetta *et al.*, 1995). This SR-TXRF takes advantage of a SR beam with over 95% linear polarization and a high degree of collimation. Further improvement to 10^7 atoms/cm^2 detection should be possible with a brighter SR source and a faster detector.

5.8 Infrared Spectroscopy

Infrared (IR) spectroscopy provides the means for analyzing the molecular chemistry of materials in detail. However, because of its longer wavelengths, IR radiation limits the spatial resolution, but its ability of resolving chemistry is extremely useful. Thus, IR microspectroscopy (IMS) has been developed in combination with light microscopy and IR spectroscopy to correlate microstructure with molecular chemistry. Synchrotron radiation source has 100–1000 times higher brilliance than a traditional thermal-emission source, and because of its nonthermal source, it produces less Boltzmann source noise. Thus, high brightness, low noise, and improved optical performance make the SR an ideal source for IMS.

A scanning IR microprobe consisting of an integrated Fourier transform infrared (FTIR) spectrometer and microscope optical module was developed (Reffner *et al.*, 1995). They adopted Schwarzschild reflecting designs as the microscopic optics using 0.65-NA (numerical aperture) and 0.58-NA objective lenses. A rapid-scan Michelson interferometer with a germanium-coated KBr beam splitter was used. Spectral resolution is from 2 to 16 cm^{-1}. The beam-profile measurement revealed that the IR beam was focused to a diffraction-limited spot size of less than 12.5 μm. Furthermore, it is found that scanning across a sharp boundary with a 6-μm-diameter aperture produced a maximum spatial resolution of 6 μm. The signal-to-noise ratio was found to be 250:1 in the IR spectra, where the total acquisition time was 5 s per spectrum.

So far, IMS, which is a basic technology for the molecular characterization of materials, has been applied in various research fields such as biological science, polymer science, earth science, forensic science, and cultural materials. In biological science, the single human hair erythrocyte was studied using FTIR microspectroscopy (Dong *et al.*, 1988). The single-cell spectrum contained all of the pertinent information about both the characteristic protein's secondary structure and bound carbon monoxide. Further studies of single red blood cells showed that different mutant forms were identifiable through IMS. In polymer science, polymer-dispersed liquid-crystal films were studied by FTIR microspectroscopy to compare the polymer and liquid-crystal droplet regions (McFarland *et al.*, 1993). Spatially resolved functional-group maps of a droplet showed characteristic textures corresponding to the visually observed morphology of the droplet. It was possible to correlate the microscopic texture with the chemistry and with the changes that occur when electric fields are applied. In earth science, synchrotron IMS provided the high signal-to-noise ratio necessary to quantitate the trace amount of hydrogen in nominally anhydrous perovskite. $MgSiO_3$ single crystals were quantitatively analyzed, which were grown directly from H_2O-rich melts of $MgSiO_3$ at a pressure of 27 GPa and a temperature of 1830 °C (Meade *et al.*, 1994). They found that the hydrogen concentration is comparable to 12% of the mass of hydrogen in the earth's atmosphere. In forensic science, a new approach to forensic analysis with IMS was performed (Bartick *et al.*, 1994). The microscopic attenuated internal-reflection spectroscopy (ATR) technique is an extension of IMS that permits the analysis of materials' surface with little or no sample preparation. This method will open a new dimension to the evaluation of forensic evidence. Thus, with SR, IMS can be performed at the diffraction limit of the IR radiation, and spectra with high signal-to-noise quality can be obtained.

6. MEDICAL AND BIOLOGICAL SCIENCE AND TECHNOLOGY

It is said that the twenty-first century is a century of bioscience or life science. SR is expected to play an important role in life science, especially in studies on biological substances in the crystalline state, the noncrystalline state, the solution state, and the amorphous state. Among various kinds of biological substances, it is believed that protein crystallography is the most important target for bioscience.

Protein is in charge of translation of heredity information, energy conversion, information transmission, action, and substance synthesis. In order to elucidate the characteristic function of a protein or nucleic acid, it is necessary to analyze the molecular structure at atomic resolution and understand how the amino-acid arrangement forms its three-dimensional structure. On the basis of this information, it becomes possible to design new functional proteins.

Furthermore, the medical diagnosis system using the *K* edge of injected iodine, contraction of muscle, *in vivo* soft x-ray microscopy, and evaluation of irradiation damage are also important subjects in life science. Without brilliant SR beams, these techniques cannot be developed.

6.1 SR Angiography

X-ray imaging and x-ray crystallography are promising for medical and biological applications. After the usefulness and prospects for practical applications in these fields were recognized, many researchers in medical industries became involved in R&D of SR analysis techniques mainly in the following four systems. One is the *K*-absorption–edge subtraction method using monochromatic x rays for a heart vascular system. The second target is the high–spatial-resolution monochromatic x-ray CT system for high-precision diagnosis of physiological circulation in the brain. The third target is the imaging examination system for the fine vascular system for early finding of malign tumor or cancer. The last target is the new imaging system with fluorescence x rays emitted from a target element for trace elements in the human body.

Among these the most promising application is the new real-time imaging technique for the heart vascular system using *K*-edge subtraction. This technique has been developed by using an iodine filter and an imaging focusing and processing system. As shown in Fig. 22, a monochromatic SR beam with photon energy below and above the iodine *K* edge irradiates an object injected with iodinated material, and real-time images are processed by subtraction to obtain clearly distinguished images of heart.

FIG. 22. Schematic diagram of the dual-energy real-time imaging system and a *K*-edge substraction image of a 12-kg dog's heart (Ueda *et al.*, 1989).

This *K*-edge subtraction system is under development for intravenous coronary angiography capable of providing a screening test for ischemic heart diseases. X-ray images of a dog taken using monochromatic x rays at above the *K*-edge energy of iodine clearly distinguished the coronary arteries 7–8 s after the iodinated contrast materials were injected into a leg vein (Ueda *et al.*, 1989). The optimal condition for transvenous coronary angiography to obtain clear images of human coronary arteries was reported (Chapman *et al.*, 1995). They used a 1200-element dual-array detector with a pixel-to-pixel spacing of 0.25 mm. In the near future this intravenous coronary angiography will be performed routinely for heart disease patients. This will need a large storage ring such as SPring-8 at 8 GeV to provide iodine *K*-edge hard x rays of about 33 keV.

The evaluation system for blood flowing in the brain is also important for diagnosis of brain tumor before and after the operation. Although the RI (radioisotope) imaging system and the magnetic-resonance imaging (MRI) system have been used for that purpose, the spatial resolution is still as poor as several millimeters. In order to improve the spatial resolution for the brain blood-flow diagnosis system, a monochromatic x-ray CT system was developed using an about 50-keV monochromatic SR beam whose width was expanded by asymmetric reflection, and a one-dimensional charge-coupled device (CCD) detector (see CHARGE-COUPLED DEVICES). The spatial resolution has reached 7 μm. Thus, the medical diagnosis system using SR is regarded as a significantly important technique for human life. In the near future, compact SR rings that are specified for these medical diagnosis systems will be developed.

6.2 Protein Crystallography

The extremely bright SR beam has opened new fields, such as structural analysis of macromolecules. Knowing their three-dimensional structures is vital for revealing the mechanism of activities of biological macromolecules such as proteins and viruses. Since biotechnology or protein engineering is expected to become a huge industry in the next century, many efforts are being devoted to establish a data bank of protein structures. For that purpose, x-ray crystallography is one of the most powerful techniques to determine three-dimensional structures of biological macromolecules at the atomic level. Nowadays new three-dimensional structures of proteins are reported in many journals such as *Nature* and *Science.* Actually, SR has drastically reduced the measurement time and enabled the measurement of small protein crystals. Furthermore, new methods to determine protein crystal structures, such as the multiple-wavelength anomalous-dispersion (MAD) method for phase calculation and a time-resolved Laue method using white x rays, have been developed.

A data collection system for macromolecular crystals using a Weissenberg camera and an imaging plate was developed at the Photon Factory at the National High Energy Physics Laboratory, Tsukuba (KEK), for high-resolution, high-precision, and high-speed data collection. It takes only a few hours to collect all the diffraction data from one crystal. Figure 23 shows a data collection system consisting of a Weissenberg camera and an imaging plate (Sakabe, 1983; Sakabe *et al.*, 1995), and Plate 2 shows an atomic model of Actin-DNase 1 complex constructed on the basis of x-ray diffraction patterns (Sasaki *et al.*, 1993). This complex consists of 634 amino-acid bases, and the total

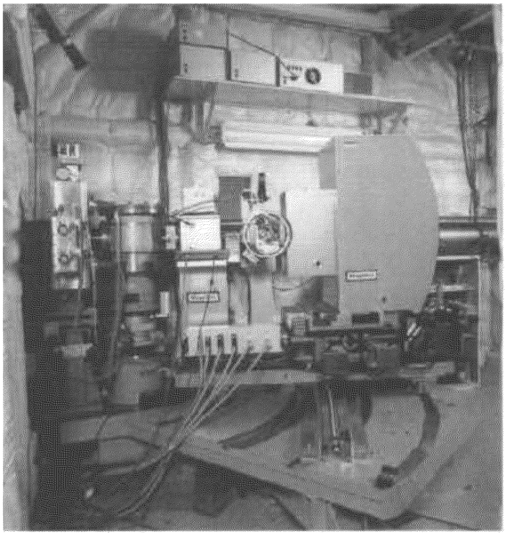

FIG. 23. A protein crystallography system with a Weissenberg camera and an imaging plate (courtesy of N. Sakabe).

molecular number is 73 000 Da. The crystal structure is rhombohedral with the space group of $P2_12_12_1$, and the lattice parameters a, b, and c are 42.0, 225.3, and 77.4 Å, respectively. This analysis was done with an extremely high resolution, 1.8 Å.

The HIV reverse transcriptase, which is an AIDS-related protein, was analyzed (Jones *et al.*, 1993). The work revealed that the space group of this crystal is $P4_222$ and that the lattice parameters a and b are 120 Å and c is 320 Å. The structure of interferon, which is an important protein for medical applications such as medicines for brain cancer and B- and C-type liver diseases, was determined (Mitsui *et al.*, 1993). A double-shelled spherical virus that has a huge molecular weight, as high as 65 200 000 Da, was analyzed (Mizuno *et al.*, 1991). Crystals of the virus belong to the space group $I23$, and the lattice parameter a is 789 Å. This result gave important information about the interaction between nucleic acids and proteins, the flexibility of proteins, and the interactions between proteins.

The very bright SR beam has also enabled dynamic structure analysis of protein crystals using white x rays. The reaction time of enzymes with their substrates ranges from sub-milliseconds to minutes in solution, while it becomes about 100 times slower in crystals. A new time-resolved Laue camera system is being developed to measure diffraction with a 10-ms exposure, where millisecond x-ray pulses together with an imaging plate that is synchronously moved are used.

Thus, SR protein crystallography is expected to open the key to understanding the mechanism of various life phenomena and to strongly support the design of new drugs.

6.3 Small-Angle X-Ray Scattering

Elucidation of the relationship between the structure change of living substances and their functions is one of the most important subjects in biophysics. Among various chemical reactions and structure changes, contraction of muscle is regarded as one of the most suitable systems for this subject, because the structure of muscle is directly correlated with the function. As shown in Fig. 24, the dominant proteins constituting the muscle are actin and myosin, and the fundamental process of muscle contraction is the interaction between the two proteins by extracting energy from the hydrolysis of adenosine triphosphate (ATP). Although the structures of actin and myosin, which are regularly arranged like liquid crystals in the form of filament, have been analyzed by x-ray diffraction, the clear answers about how actin and myosin interact, how the structure change happens, and how they are correlated with the generation of tension have not been obtained yet.

In order to answer these questions, small-angle x-ray scattering using SR has been utilized for understanding the dynamic processes of chemical bonding between actin and myosin, and the transfer of chemical energy to molecules on an atomic scale. Furthermore, the mechanisms of the structure change of regulatory proteins (such as troponon and tropomyosin) by Ca ions and the information transfer to contractile proteins should be also elucidated on a molecular scale.

Time-resolved analysis of the intensity change of a specific diffraction spot together with the generation of tension can provide important information. The myosin heads were found to bond to actin during contraction by measuring the 5.9-nm reflection corresponding to the pitch of the left-handed screw of actin filament and the 5.1-nm reflection corresponding to the pitch of the right-handed screw of actin filament (Wakabayashi *et al.*, 1985). In this experiment, a one-dimensional position-sensitive proportional counter (PSPC) with the time resolution of millisecond order was used.

In order to realize more precise analysis of the structure change during muscle contraction and relaxation, a new two-dimensional detector system called an imaging plate, which consists of a photostimulated phosphor, was introduced (Amemiya and Miyahara, 1988). This system has a large dynamic range of more than five orders of magnitude. By using this system, x-ray diffraction images of frog skeletal muscle during contraction and relaxation were obtained with exposure time as short as 10 s with high spatial resolution. They found that the reflection corresponding to the helical structure of the myosin heads is drastically decreasing during contraction, but the 14.3-nm meridional reflection of the myosin heads showed a strong intensity. These results in-

dicate that myosin heads move toward the azimuthal direction but still interact with actin with a 14.3-nm periodicity along the actin filament axis.

Furthermore, more precise analysis of actin reflection, which is extremely weak (about 10^{-4} of the equatorial reflection), revealed that the actin filament is extended by 0.3–0.4% during contraction and that the energy from ATP, which is decomposed at the myosin heads, causes a structure change of myosin heads themselves and is converted into the elastic energy to extend actin.

Thus, many important phenomena have been discovered by the SR small-angle x-ray scattering method, and a real image of the muscle contraction mechanism is being elucidated. However, these measurements provide information about averaged phenomena in several tens of thousands of fibers. In the near future, time-resolved measurement of a single muscle fiber of about 100 μm in diameter would be realized by development of a more brilliant SR beam and higher-sensitivity x-ray detectors in order to provide information about the correlation between ATP decomposition and mechanical response of molecular structure.

6.4 *In Vivo* Soft X-Ray Microscopy

X-ray microscopy can directly analyze living biological substances in water. It is well known that water has a window between the O *K* edge (about 530 eV) and the C *K* edge (about 280 eV), which is the useful energy region for analyzing living biological samples using soft x rays. Soft x-ray microscopy has several advantages over electron microscopy. First, the sharp x-ray absorption dependence on elements and/or wavelength enables one to realize microscopy that is sensitive to elemental composition. Second, specimens can be observed directly in their natural state without any fixing and staining.

A new imaging technique taking advantage of this water window has been developed by using a Fresnel zone plate (FZP). The FZP is a circular transmission diffraction grating consisting of alternating opaque and transparent rings. It gives a spatial resolution almost equal to its outermost zone width. The FZPs are fabricated by using the current ULSI microprocessing technology such as electron-beam lithography and reactive-ion etching. Since the outermost zone is about 50 nm wide, a corresponding resolution of about 50 nm can be expected (Rarback *et al.*, 1990).

As an example of scanning x-ray microscopy (SXM), the SXM images of a chromosome taken at the photon energies below and above the C *K* edge were shown to be different from each other, indicating that chemical-state mapping is possible by changing the wavelength to discriminate successfully C=O bonds from C—N bonds in DNA (deoxyribonucleic acid) (Ade *et al.*, 1992). A two-dimensional Ca distribution in mineralized tissues was obtained by the absorption-difference imaging method at the Ca *K* absorption edge (Buckley, 1995). If the photon energy can be increased up to the Al *K* edge (about 1.56 keV), it is possible to obtain the Al distribution in brain cells, which may be correlated with the Alzheimer disease.

In contrast, the highest spatial resolution in soft x-ray microscopy was achieved by means of an imaging x-ray microscope (IXM) using the FZP system. Very clear IXM images of Kupfer cells of rat liver were obtained using the phase-contrast method (Schmahl *et al.*, 1995). Thus, soft x-ray microscopes are expected to open new medical and biological fields.

6.5 Irradiation Effects on Biology

Radiobiology is an important field from the viewpoints of radiotherapy of cancer using heavy particles and protection from environmental radiation of low dose rates. Radiobiological effects are induced with energy deposited by radiation. The deposition events occur randomly and discretely. The average amount of energy deposited per event is about 30 eV, which produces two ion pairs on average. The consequences of each energy deposition event should be understood. Although deactivation processes take place, molecular changes produce the biological damage. We also have to understand how these consequences change depending upon the density of energy deposition events in space and time through the interaction of the reactive species produced by them.

In order to elucidate these radiation processes, it is necessary to deposit energy into biological samples in a well-controlled manner. One way is to irradiate samples with low-energy monochromatic photons. Since vacuum ultraviolet photons of about 40-nm wavelength give an energy quantum of about 30 eV around the absorption site, it is possible to study the processes and their efficiencies in producing molecular changes induced with this energy. In the higher photon-energy region, the processes of absorbing energy by *K*-shell electrons of oxygen in water molecules contained in living cells occur, and a shower of almost monoenergetic electrons is produced in the cells.

Using plasmid DNA, it was revealed that the base damage recognized by an UV endonuclease (with specificity for pyrimidine dimers) was not produced by photons below 180-nm wavelength and that single-strand breaks (SSB) were produced more effectively with shorter-wavelength photons (Hieda *et al.*, 1994). It was noted that the action spectrum of SSB production was similar to that of the absorption of the sugar-phosphate moiety of DNA, indicating that SSB might be produced along with the photoabsorption of the backbone (sugar) of DNA. Further studies using dinucleotides have revealed that SSB is produced associated with the destruction of the sugar moiety, releasing fragments having a 5′ phosphate end (Ito, 1991). Recently the energy dependence for the production of SSB and of double-strand breaks (DSB) in pBR322 DNA was shown in the energy region from 60 to 550 eV (Hieda, 1994). The yield for DSB increased with the increase in photon energy, when compared with the yield for SSB. Thus a photon energy of about 300 eV is needed for DSB induction.

At a higher-energy region, most works have been focused on photoabsorption at the *K* shell of phosphorus in DNA because of the strategic position in the biologically important molecule, taking advantage of the complete tunability of SR. The enhancement in the biological effects at the resonance absorption peak can be considered to be initiated by the photoabsorption by phosphorus. This enhancement was observed in several organisms including lethality and induction of genetic changes in yeast, lethality in bacteria, chromosome aberration in mammalian cells, and mutation and killing in mammalian cells (Kobayashi *et al.,* 1991).

As a close simulation of aqueous systems, SSB and DSB were measured with the plasmid DNA irradiated in aqueous solutions. Strand-break yields were shown to be enhanced by the photoabsorption of phosphorus in the DNA molecule. Similar enhancements were observed for the release of adenine from ATP in a concentrated aqueous solution. These data suggest that water molecules may play an important role in the production mechanisms of the damage in aqueous systems.

Further studies on molecular mechanism of biological action using inner-shell ionization and energy dependence of molecular change due to SR irradiation ranging from VUV to x rays should be done to understand the radiobiology mechanism.

7. FUTURE PROSPECTS

Based on more than 30 years of experience in SR research, third-generation SR sources have been constructed or are now being constructed, including high-energy SR sources such as ESRF (6 GeV, Grenoble, France), APS (7 GeV, Chicago, Illinois, U.S.A.), and SPring-8 (8 GeV, Nishi-Harima, Japan). Furthermore, medium-energy SR sources of the third generation such as ALS (Advanced Light Source at U.C. Berkeley, California, U.S.A.), Super ACO (Paris, France), PLS (Pohang Light Source, Pohang, Korea), SRRC (Synchrotron Radiation Research Center, Hsinchu, Taiwan), and Elettra (Trieste, Italy) with energies of about 1–2 GeV are now available for experiments with a very low emittance.

These advanced storage rings together with undulators (linearly and circularly polarized), high-efficiency monochromators, and high-throughput optics will make it possible to focus the SR beam to much less than 0.1 μm with extremely high energy resolution, greater than 10 000. Thus, experiments with high spatial resolution, time resolution, energy resolution, and circular polarization will become possible, leading to complete understanding of phenomena in materials and life sciences and new development of atomic-scale characterization, real-time process monitoring, and advanced fabrication processes using SR-excited film growth and etching. Furthermore, new physical or electronic properties such as quantum size effects in quantum nanostructures will be discovered. These advanced SR techniques will be also combined with other advanced tools such as STM, focused ion beams, electron beams, and laser beams in a complementary manner in order to discover novel phenomena and control properties on an atomic/molecular scale.

ACRONYMS

ALE: Atomic layer epitaxy.

ATP: Adenosine triphosphate.

ATR: Attenuated internal reflection.

CCD: Charge-coupled device.

CT: Computed tomography.

CVD: Chemical vapor deposition.

CZ: Czochralski method.

DMAH: Dimethyl aluminum hydride.

DNA: Deoxyribonucleic acid.

DRAM: Dynamic random access memory.

EXAFS: Extended x-ray absorption fine structure.

FZ: Floating zone method.

FZP: Fresnel zone plate.

GID: Grazing-incidence diffraction.

GSPC: Gas-scintillation proportional counter.

IMS: Infrared microspectroscopy.

LIGA: German acronym for three basic processes of deep-etch lithography with synchrotron radiation, electroforming, and plastic molding.

LPE: Liquid-phase epitaxy.

MBE: Molecular-beam epitaxy.

MESFET: Metal-semiconductor field-effect transistor.

MISFET: Metal-insulator-semiconductor field-effect transistor.

PCX-CT: Phase-contrast x-ray computed tomography.

RHEED: Reflection high-energy electron diffraction.

SBH: Schottky-barrier height.

SRPES: Synchrotron-radiation photoelectron spectroscopy.

SSB: Single-strand break.

TBA: Tertiarybutylarsine.

TEM: Transmission electron microscope.

TMG: Trimethylgallium.

TOF: Time-of-flight.

TXRF: Total x-ray reflection fluorescence.

ULSI: Ultralarge-scale integration.

UHV: Ultrahigh vacuum.

UPWT: Ultraplane-wave topography.

VUV: Vacuum ultraviolet.

XAFS: X-ray absorption fine structure.

XANES: X-ray absorption near-edge structure.

XFA: X-ray fluorescence analysis.

XSW: X-ray standing waves.

GLOSSARY

Micromachine: Mechanical system with the size of less than millimeters, usually consisting of microactuators, microsensors, and microprocessors. Micromechanical parts such as microgears, micromotors, etc. are also called micromachines.

Photochemistry: Chemical reactions induced by photoabsorption, not thermal effect. Lithography and photo CVD are examples. There are two types of photochemical reaction: one is the direct excitation of valence electrons by several-eV photons such as lasers or halogen lamps, and the other is core-electron excitation followed by Auger de-excitation, which takes place by SR irradiation.

Photoelectron Spectroscopy: A form of electron spectroscopy for measuring the energies of core-level and valence electrons that are emitted from atoms or solids when monochromatic x rays or VUV photons are absorbed.

Storage Ring: A circular vacuum ring to store charged particles such as electrons or positrons moving with extremely high speed, close to the speed of light, to produce synchrotron radiation.

Synchrotron Radiation: A kind of bremsstrahlung radiation emitted in the forward direction tangential to the orbit when charged particles such as electrons are forced to move at speeds close to the speed of light in a circular orbit.

Tomography: The use of x rays to photograph a selected plane of a human body with other planes eliminated. The computerized tomography scanner is a ring-shaped x-ray machine that rotates through 180°. A three-dimensional image of the tissues under examination is formed.

X-Ray Absorption Fine Structure: Technique to provide information about the short-range order such as the number, types, and distances of neighbors by analyzing the x-ray absorption spectra at energies higher than the absorption edge of the target atom. XAFS is useful in analyzing amorphous materials, surfaces, and so on.

X-Ray Diffraction: Diffraction phenomena of x rays as an electromagnetic wave in crystals, which can be used to determine structures of crystals including protein crystals by means of x-ray diffraction camera and diffractometers.

X-Ray Microscopy: Microscopy using soft x rays with photon energy between the carbon K edge and the oxygen K edge mainly for biological specimens. There are two types of x-ray microscopes, namely, the projection type and the scanning type.

18.1
Introduction

The synchrotron is a particle accelerator, in which charged particles take a circular orbit and are accelerated to a high energy during circulation. Among other circular accelerators, the synchrotron method is, at present, unique in that it enables charged particles to be accelerated to energies of about 1 TeV. Both electron and proton synchrotrons have been mostly employed in basic research, especially in high-energy physics. They have also played essential roles in the advance of charged-particle acceleration techniques. The synchrotron is closely related to storage rings and the development of the colliding-beam method. Since the acceleration principle of storage rings is basically the same as that of the synchrotron, they have a similar configuration to that of synchrotrons. Beams are injected into a storage ring from a linear accelerator (linac) or a synchrotron after preacceleration. Synchrotrons accelerate the beam with a high repetition rate (up to 50 Hz). Storage rings and colliders can also accelerate, but at much slower rates.

Initially, storage rings were prominently used for particle colliders, in which two particle beams traveling in opposite directions are made to collide. The particles used in such experiments are electrons (positrons), protons (antiprotons), and heavy ions. Storage rings also serve as particle accumulators in which successive particle bunches from an injector are stacked so as to store relatively high-current beams. They are also used for beam cooling.

Although the synchrotrons, as well as other particle accelerators, are developed for the purpose of particle physics, the applications of synchrotrons have expanded to a wide variety of research fields, such as materials science, medical and biological sciences, and studies in radiotherapy. Besides basic research, synchrotrons are now also being used for industrial applications.

New technological developments have boosted the progress of accelerators, and there are now a great many technological spinoffs. For example, new large synchrotrons require high-field superconducting magnets that push further development of superconducting materials. The requirement of an extremely low pressure in storage-ring vacuum chambers having very large dimensions has greatly stimulated high-vacuum technologies. The accurate control of a large number of accelerator components was followed by progress in computer technology,

ISBN: 978-3-527-40691-3

which in turn stimulated progress in these fields.

18.2
Brief History

As the acceleration energy increased, accelerator technologies have inevitably encountered practical limitations in both size and cost. The linac has reached some practical construction limit because of its length. Lawrence (1930) proposed a circular-acceleration method that can conveniently overcome this problem of length by accelerating particles in a circular path maintained by magnetic fields. Charged particles move in a spiral orbit in a homogeneous magnetic field such that they are accelerated many times while traversing an accelerating gap. Since the revolution period is independent of the particle energy in the nonrelativistic approximation, the frequency of the acceleration field is kept constant. This machine, called the *cyclotron*, was first built by Livingston (1931), who demonstrated the principle by accelerating hydrogen ions to 80 keV.

However, as the particle energies increased further, the normal cyclotron method reached its limit, because relativistic effects caused the synchronism of the accelerating field to be lost. A *synchrocyclotron* is an accelerator in which a synchronous acceleration method is applied to a cyclotron. Many such machines were built for energies in the 100–1000 MeV range. The cyclotron, or synchrocyclotron, is arranged so as to provide a constant magnetic field over relatively large areas, which allow the particles to travel in a spiral orbit of gradually increasing diameter as they increase in energy.

Kerst and Serber (1941); Kerst (1941, 1942) proposed a circular accelerator called a *betatron*, which utilizes a time-varying magnetic field that, in turn, produces an electric field for acceleration through induction, which has been used only for the acceleration of electrons. The betatron comprises a doughnut-shaped vacuum chamber for the beam path located between the poles of an electromagnet. The magnetic field acts to bend the electron beams in a circular orbit and to induce a voltage that accelerates the electron tangentially to the orbit. They are limited to acceleration not much above 300 MeV.

McMillan (1945) and Veksler (1945) independently discovered the principle of *phase stability* and invented the *synchrotron*. In the synchrotron, the guide field increases with particle energy so that the beam takes a circular orbit, and acceleration takes place owing to a radio-frequency (rf) electric field, rather than an induction field, as in the case of betatrons.

In early synchrotrons, the focusing fields were weak quadrupole fields superimposed on dipole magnetic fields; this is called the *weak-focusing* method. The first such synchrotron, the 3-GeV Cosmotron at Brookhaven National Laboratory (BNL), was built in 1952; the largest of these is the 10-GeV Syncrophasotron at Dubna.

Modern synchrotrons use a *strong-focusing* method, usually by means of separate quadrupole magnets that constrain the particles to a narrow path. A pair of such magnets exerts a net focusing force in both the vertical and horizontal directions. These strong-focusing machines are known as *alternating-gradient* accelerators. The method of the alternating-gradient synchrotron (AGS) was discovered by Christofilos (1950), and independently by Courant, Livingston, and Snyder (1952); see also Courant and Snyder (1958). The invention of the strong-focusing method resulted in a real breakthrough

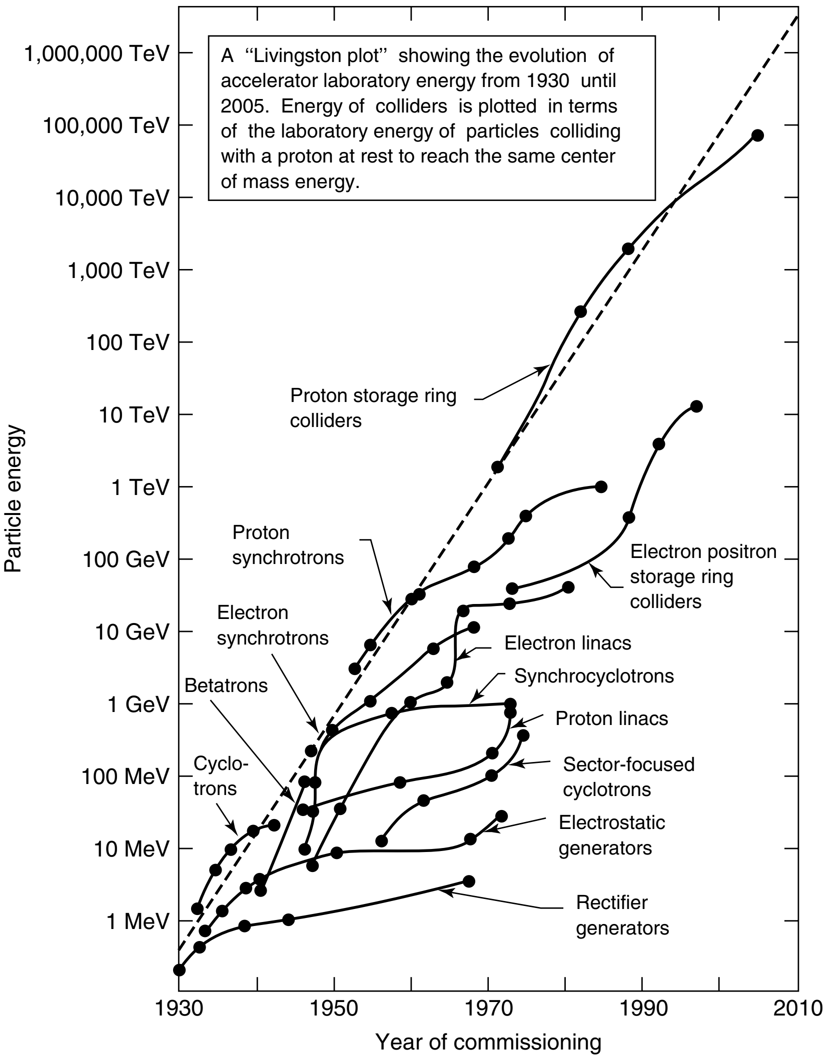

Fig. 18.1 "Livingston chart" showing the maximum energy as a function of the year for various accelerator technologies.

in synchrotrons. In this method, since particles are able to travel in a narrow beam chamber, the sizes as well as the construction costs of the synchrotron magnets became considerably reduced. This overcame the practical limitations of the particle energy and pushed machines to higher energies; synchrotrons having energies above 10 GeV could thus be constructed. The AGS at BNL was the first synchrotron using this method and was built in 1961. In this machine, protons are accelerated up to 33 GeV. The first two synchrotrons of this type were *combined-function* accelerators; the bending magnets had additional quadrupole-field components. Modern synchrotrons are built with *separate-function* type magnets. Simple dipole magnets are used for bending the particle path, and quadrupole magnets are used for focusing the beam. The two largest synchrotrons for protons are the Large Hadron Collider (LHC) (7 TeV) at European Laboratory for Particle Physics (CERN) and the Tevatron (900 GeV) at Fermi National Accelerator Laboratory (FNAL).

For high-energy physics experiments, accelerated particles in a synchrotron are extracted and bombarded onto atoms in a fixed target. The efficiency of the energy used for this process rapidly decreases as the particle energy increases. This is because a large part of the energy of a particle colliding with a fixed atom is wasted in the forward motion of both particles, that is, in the direction of motion of the incident particle; a small part is converted into the relative motion of the two particles.

On the other hand, in the *colliding-beam* method the efficiency of the accelerated-particle energy utilization has been drastically increased, particularly in very high energy collisions. Two independent bunches of particles accelerated in synchrotron(s) are injected into storage ring(s); those bunches travel in opposite directions and make head-on collisions.

Figure 18.1 is a ‘‘Livingston chart,’’ which shows the maximum energy as a function of the year for various accelerator technologies. Cockcroft and Walton accelerated protons to about 400 keV using a static high-voltage (700 keV) generator (1932). Since then, dramatic progress has been achieved in various accelerator technologies. The inventions of the linac and circular-acceleration methods, such as cyclotrons, synchrocyclotrons, betatrons, and synchrotrons, have brought about great progress in particle energy. The maximum particle energies increased by more than one and a half orders of magnitude during one decade (in storage-ring colliders, the energies are given as the energies that would be needed in a fixed-target machine to provide the same available interaction energy).

Although synchrotrons and storage rings with very high energies belong almost exclusively to the field of high-energy physics, they have played a prominent role in utility applications. The development of intensive neutron sources and synchrotron-radiation sources, which are becoming ever more important in various fields of materials science and industrial technologies, has been made possible by advances in synchrotron and storage-ring design.

18.3
General Principles

18.3.1
Operating Principle

Figure 18.2 is a schematic illustration of a synchrotron. Charged particles are injected into a synchrotron chamber provided

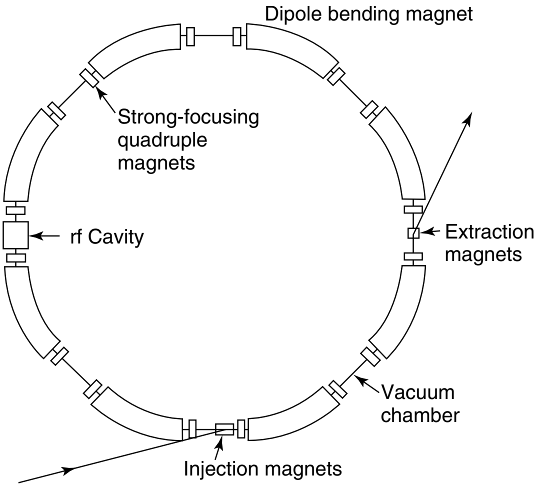

Fig. 18.2 Schematics of a synchrotron accelerator.

with a number of electromagnets to bend the particle path by the Lorentz force. The injection beams come from a preaccelerator, such as a linac. In rf cavities, acceleration takes place with electric fields supplied from rf-power sources, which commonly operate at between several and several hundred megahertz. In a synchrotron, particles take an orbit having a constant radius, like in a betatron, nominally at the center of the beam pipe around the circumference of the synchrotron.

Figure 18.3 shows the operating cycle of a synchrotron. After injection is completed, the dipole magnetic field (B) increases linearly, thus causing the particles to stay in a constant orbit as their energy (E) increases. Here, E is the total energy ($E^2 = (pc)^2 + (mc^2)^2$, where p is momentum of a particle, m its rest mass, and c the speed of light). Since protons or ions, which are much heavier than electrons, gain velocities relatively slowly, frequency modulation of the rf accelerating voltage has to be applied to make certain that the accelerating voltage and frequency of particle revolution are synchronous. Therefore, during a single acceleration cycle (when particles take a circular orbit), both the magnetic field (B) and the rf frequency (f) increase as

$$f = \frac{ec^2 B}{2\pi E} \tag{1}$$

Since in an electron synchrotron the particles are injected at a kinetic energy higher than some tens of megavolts, they always have a velocity close to the speed of light. As a consequence, the revolution frequency of the particles is almost constant, and it is possible to use a fixed-frequency accelerating cavity. This is one of the primary differences between electron synchrotrons and proton synchrotrons, where the frequency of the accelerating rf fields must be adjusted during acceleration by a factor of 10 or more, because the velocity of the much heavier protons at typical injection energies is much slower than that of light.

At the end of the accelerating cycle (Figure 18.3), accelerated particles are either directed at an internal target in the accelerator chamber or are extracted outside and guided to experimental

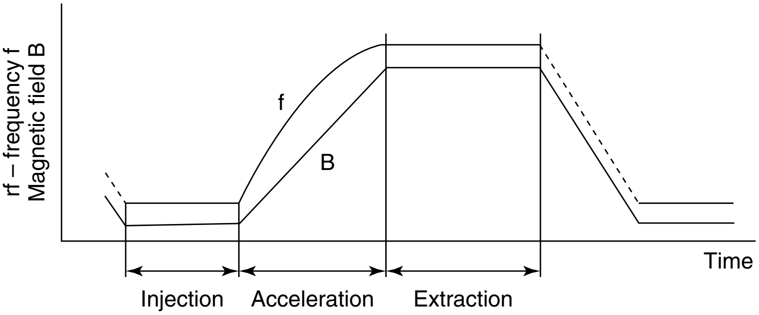

Fig. 18.3 Typical operating cycle of the magnetic field and acceleration frequency of a proton synchrotron.

stations, or to additional accelerators. In a large proton synchrotron, the cycle lasts for between a few seconds and a few tens of seconds.

18.3.2
Particle Motion in a Circular Accelerator

Practically, since circulating particles have a small transverse momentum, they oscillate around an ideal circular orbit with a frequency determined by the focusing force of the magnetic fields. This motion is known as the *betatron oscillation*, and the frequency is called the *betatron frequency*.

We assume that the circular accelerator has a median plane, taken to be the horizontal plane ($y = 0$). The bending fields are perpendicular and the focusing fields are perpendicular or parallel to this plane. There is a closed orbit in this plane, called the *equilibrium orbit*, on which a particle with reference momentum p_0 can circulate. The trajectory of an arbitrary particle is characterized by its coordinates: x, y, and s, defined by Figure 18.4

The equation of motion of $x(s)$ and $y(s)$ can be obtained from the Lorentz force. If all terms of higher order than the first are neglected (linear approximation), the equations take the form

$$\frac{d^2x}{ds^2} - \left[k(s) - \frac{1}{\rho^2(s)}\right]x = \frac{1}{\rho(s)}\frac{\Delta p}{p_0},$$
$$\frac{d^2y}{ds^2} + k(s)y = 0 \qquad (2)$$

Here, $\rho(s)$ is the radius of curvature due to the dipole fields, and $k(s)$ defines the focusing strength due to the quadrupole fields:

$$k(s) = -\frac{1}{B\rho}\frac{dB_y}{dx} \qquad (3)$$

An important property of the quadrupole magnet is that when the force is focusing in the horizontal plane, it is defocusing in the vertical plane, or vice versa. Note that both $k(s)$ and $\rho(s)$ are periodic functions of s; $\Delta p/p_0$ is the momentum error of the particle. While discussing betatron oscillations, we put $\Delta p/p_0 = 0$. In this case, both equations have the same form:

$$\frac{d^2u}{ds^2} + K(s)u = 0 \qquad (4)$$

where $K(s)$ depends on the plane under consideration and $u(s)$ means $x(s)$ or $y(s)$. Since the equilibrium orbit is closed, $K(s)$

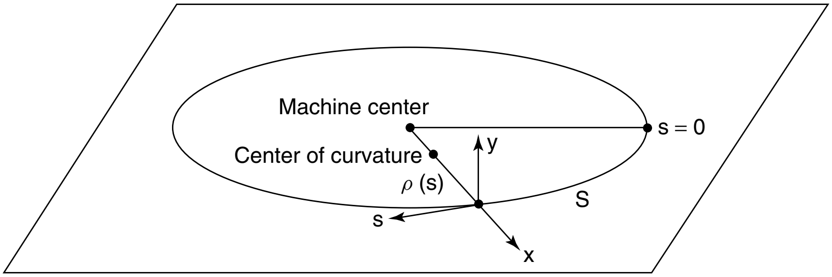

Fig. 18.4 Coordinate system for description of beam.

is a periodic function with a period of the machine circumference (L),

$$K(s+L) = K(s) \tag{5}$$

(If the machine has N identical sections of length $l(L = Nl)$, $K(s)$ satisfies the periodic condition $K(s + l) = K(s)$.)

A particle trajectory is described by a solution of the differential equation (4), which is called *Hill's equation*. According to standard convention, we use the general solution in the form

$$u(s) = A\sqrt{\beta(s)}\cos[\psi(s) + \delta] \tag{6}$$

Substitution of the general solution into the differential equation gives a relation between $\beta(s)$ and $\psi(s)$:

$$\psi(s) = \int_0^s \frac{ds}{\beta(s)} \tag{7}$$

Here, $\beta(s)$ is called the *β-function*, which is interpreted as the local wavelength of the oscillation divided by 2π. In particular, the number of oscillations per turn,

$$\nu = \frac{1}{2\pi}\int_0^L \frac{ds}{\beta(s)} \tag{8}$$

is called the *betatron tune* of the accelerator.

Most high-energy accelerators use a periodic sequence of quadrupole magnets of alternating polarity. Such configuration is called a FODO lattice, in which charged-particle beams are focused or defocused by quadrupole magnet fields. An example of the β-function and particle trajectories is shown in Figure 18.5 in a regular FODO lattice, in which quadrupole are arranged repeatedly, such as equally spaced focusing and defocusing lenses.

Each time that particle passes position s in the ring, its betatron oscillation appears as a point on an ellipse, as shown in Figure 18.6, where $u(s)$ and $du(s)/ds$ are plotted in the abscissa and ordinate, respectively. Since the area of the ellipse is invariant when the particle moves around the accelerator, we obtain the important result that the area of the ellipse enclosing the beam in phase space is invariant (*Liouville's theorem*). This is true under the condition that stochastic effects like beam–gas scattering or radiation can be neglected. The area ($\pi\varepsilon$) is an important quantity, and ε is called the *emittance*.

Practically, particles in a synchrotron have some energy spread, that is, $\Delta p/p_0$ is not zero. In this case, the motion of a particle is described by the inhomogeneous Hill's equation for the horizontal motion (Eq. (2)). Since the particle orbit in bending magnets is determined by the momentum of each particle, there is a radial spread of particles in the beam. The shift in the radial position from the central orbit is related to

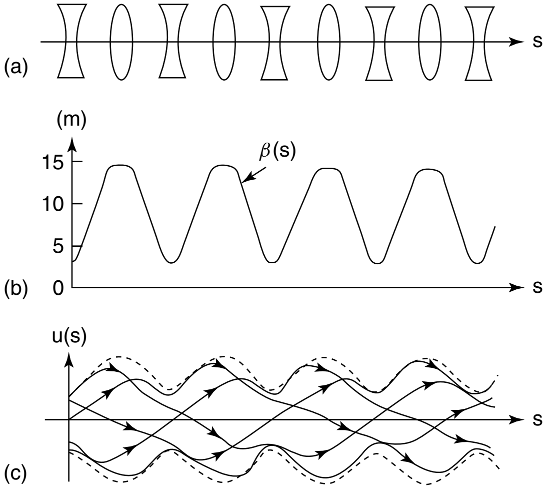

Fig. 18.5 (a) A regular FODO lattice of focusing and defocusing lenses. (b) β-Function. (c) One trajectory on several revolutions (according to Sands (1970)).

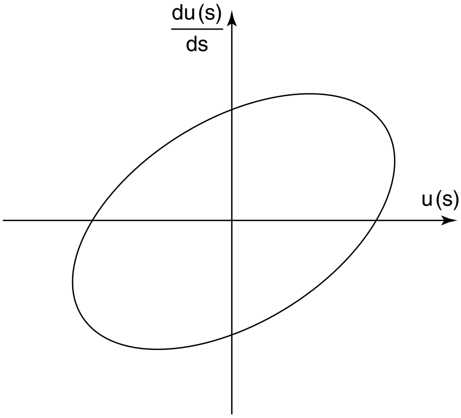

Fig. 18.6 Phase-space ellipse at point *s*.

the momentum deviation as

$$\Delta x(s) = \eta(s)\left(\frac{\Delta p}{p}\right) \tag{9}$$

Here, $\eta(s)$ is called the *dispersion function*.

Although a more rigorous treatment has to be made, the transverse beam size and divergence can be derived using the β-functions, dispersion functions, and emittances in both planes. In electron (positron) storage rings, although the emission of synchrotron radiation determines the beam emittance (Section 18.3.7), the beam size $(\sigma_x(s), \sigma_y(s))$ can be written as

$$\sigma_x(s) = \left[\beta_x(s)\varepsilon_x + \eta(s)^2\left(\frac{\Delta p}{p}\right)^2\right]^{1/2}$$

and

$$\sigma_y(s) = \left[\beta_y(s)\varepsilon_y\right]^{1/2} \tag{10}$$

When the particles are accelerated, the emittance decreases inversely proportional to the momentum. This can be interpreted as meaning that only the longitudinal component of the momentum vector is increased during acceleration, whereas the transverse components remain invariant, so that the angular divergence decreases (*adiabatic damping*).

Here, we define the *normalized emittance* as $\varepsilon_n = (p_0/mc)\varepsilon$. For proton and heavy-ion beams, and for electron beams in linacs, the normalized emittance stays constant during acceleration. It even remains invariant when the beam is passed from an ion source through a whole chain of preaccelerators into a storage ring, provided the transitions are properly matched.

In electron (positron) storage rings, the emission of synchrotron radiation and the subsequent reacceleration are the dominant factors in determining the beam dimensions. In an ideal flat ring with complete decoupling of horizontal and vertical motion, the vertical emittance tends to zero while the horizontal emittance grows with the square of the energy.

18.3.3
Influence of Field Errors and Working Point on Resonance Diagram

In practical machines, bending magnets and quadrupole magnets are not ideal but have some field imperfections, and they contain more higher order field components due to sextupole and octupole magnets (the role of sextupole and octupole magnets is described in, for example, Rossbach and Schmüser, 1994). These higher order field components disturb ideal betatron motions. Dipole errors lead to amplitude growth of betatron oscillations at the point where the betatron tunes ν_x, ν_y (defined in the horizontal and vertical planes, respectively) are integer values, quadrupole errors excite at half-integer values, and sextupoles at one-third-integer values. One has a coupling between the horizontal and vertical betatron oscillations due to a misalignment of the quadrupoles or sextupoles. In more general terms, if tunes are based on a relation such as

$$l\nu_x + m\nu_y = n \quad (l, m, n = 0, \pm 1, \pm 2, \ldots) \tag{11}$$

the amplitudes of the oscillations can become large. This numerology defines the so-called *betatron resonance*. Figure 18.7 is a resonance diagram; one has to choose the working point (ν_x, ν_y) with a reasonable separation from the most dangerous resonance lines.

18.3.4
Phase Stability

The acceleration field in the rf cavity must be in the accelerating phase every time a particle bunch arrives. Thus, the time taken for a bunch to make one cycle around the ring circumference (revolution period of T) must be an integral multiple of the rf period. The voltage in the rf cavity is

$$V(t) = V\sin(2\pi ft) \tag{12}$$

Each particle gains an energy of ΔE, where

$$\Delta E = eV\sin\varphi \tag{13}$$

Here, φ is the phase of the rf voltage at the moment of particle passage through the cavity and is called the *acceleration phase*.

To maintain a particle on the same orbit, the magnetic field (B) is varied as

$$\frac{dB}{dt} = \frac{\Delta E}{2\pi e\rho R} \tag{14}$$

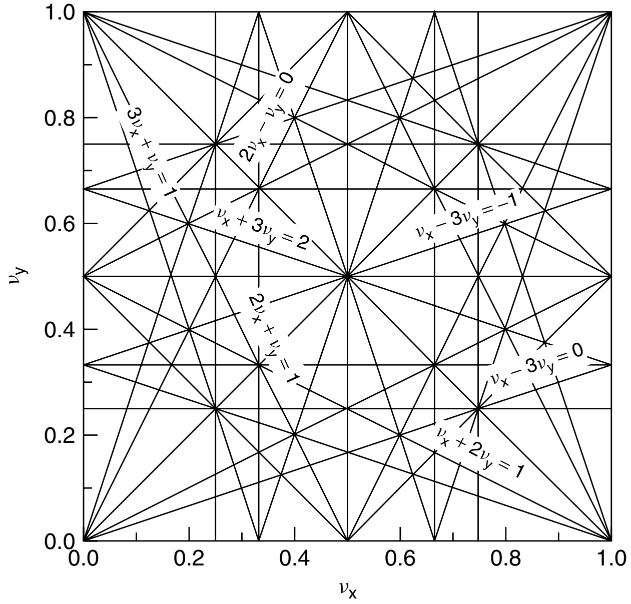

Fig. 18.7 Resonance lines in a unit square of betatron tune plane for the fourth integer and below.

where ρ is the bending radius ($\rho = p/eB$) and R is the average radius of the ring ($R = L/2\pi$; here, L is the length of the nominal orbit in circumference). The acceleration phase that satisfies these two equations is called the *equilibrium phase* or *synchronous phase*. In a synchrotron, particles oscillate in phase around the synchronous phase (φ_s) because of the focusing property of the phase (*phase stability*); they also oscillate in energy around the central energy (E_s). This oscillation in both phase and energy is called *synchrotron oscillation*.

The voltage in the accelerating gaps generally has a sinusoidal variation with time, as Eq. (12). When the equilibrium phase (φ_s) is between $\pi/2$ and π, it means that rf voltage decreases with time, and a particle at point A having an energy of E_s of which the phase (φ) is ahead of φ_s acquires more energy than at the equilibrium-phase point S ($\Delta E > \Delta E_s$), as shown in Figure 18.8(a). Since a particle having a higher energy takes a larger orbit radius and takes a longer time for one revolution, the particle at A tends to come close to point S and then go across it. The phase (φ) is behind φ_s in this case; the particle, in turn, obtains less energy than at point $S(\Delta E < \Delta E_s)$, and the particle energy tends to decrease until below E_s. Then, the phase (φ) begins to return to point A. This means that particles are not very far apart from the equilibrium phase and energy (φ_s and E_s) during acceleration. A particle takes, roughly speaking, an elliptical trajectory (Figure 18.8(b)) on the phase–energy plane (φ–E plane). Figure 18.8(c) shows the particle trajectory in longitudinal phase space in more detail. A curve that crosses

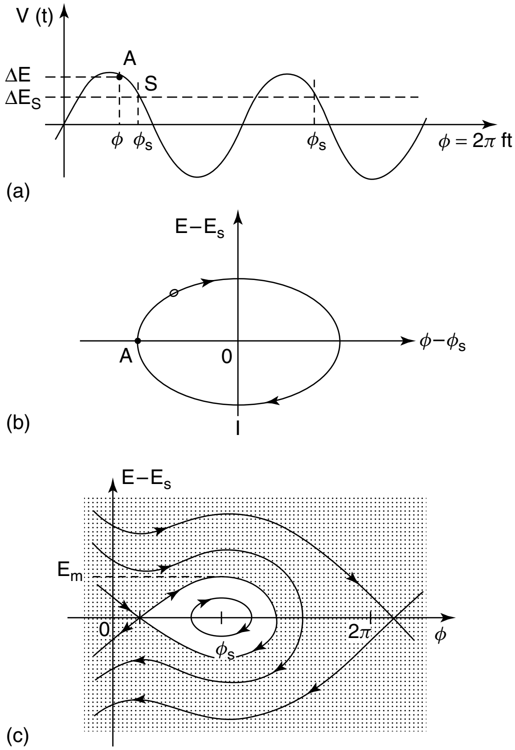

Fig. 18.8 (a) Accelerating voltage and particle phase. (b) Particle trajectory on the $\phi - E$ plane (longitudinal phase space). (c) Particle trajectory of the synchrotron motion above the transition energy in longitudinal phase space in more detail. In the shaded region, particles are unstable.

an unstable point (shaded region in the figure) is called a *separatrix*. The stable region surrounded by the separatrix is called an *rf bucket*, and the energy (E_m) of the rf bucket is called the *bucket height*. These explanations are restricted to the case that a particle energy is above the transition energy (see the next section). Below the transition energy, similar discussions are made when the equilibrium phase (φ_s) is between 0 and $\pi/2$.

18.3.5
Momentum Compaction Factor, Transition Energy

There is a closed orbit for every value of the particle momentum p; this orbit is called the *equilibrium orbit* in each momentum. The length L of the equilibrium orbit during one revolution varies with the momentum; the relation between the deviation in momentum from p and that in the equilibrium orbit length is written as

$$\frac{\Delta L}{L} = \frac{\alpha \Delta p}{p} \tag{15}$$

where the constant α is called the *momentum compaction factor*, which gives the dependence of the equilibrium orbit length on the momentum of the particles. In standard circular accelerators, α is positive. Although the value depends on the focusing methods, it is approximately given as the inverse square of the horizontal betatron tune. In weak-focusing synchrotrons $\alpha > 1$, and in strong-focusing synchrotrons $\alpha < 1$.

The revolution period T equals L/v, where v is the particle velocity. Therefore, the relation among small deviations in these quantities is given by

$$\frac{\Delta T}{T} = \frac{\Delta L}{L} - \frac{\Delta v}{v} \tag{16}$$

Using the relation

$$\frac{\Delta v}{v} = \left(\frac{1}{\gamma^2}\right)\frac{\Delta p}{p} \tag{17}$$

between the velocity and momentum (here, $\gamma = E/mc^2$), we obtain

$$\frac{\Delta T}{T} = \left(\frac{\alpha - 1}{\gamma^2}\right)\frac{\Delta p}{p} \tag{18}$$

This is an important relation for discussing the stability in rf acceleration. At low energies, $\alpha - 1/\gamma^2$ is negative, and the revolution period T decreases as the particle momentum p increases. On the other hand, when the particles exceed a certain energy, called the *transition energy*, $\alpha - 1/\gamma^2$ becomes positive. Then, the relation between T and p becomes reversed to that mentioned above; as the momentum becomes higher, a particle takes a longer time to undergo one revolution. During the acceleration process, at the moment that particles pass the transition energy, the value of the equilibrium phase suddenly makes a big change. At the transition energy, the phase stability condition is unsatisfied, the bunch length becomes short, and the momentum spread increases. The transition energy is approximately given as the horizontal betatron tune times the rest mass of the accelerating particle.

This phenomenon occurs only in strong-focusing proton (or ion) synchrotrons, because weak-focusing machines have $\alpha > 1$, and, therefore, $\alpha - 1/\gamma^2$ is always positive. For electron synchrotrons, particles are usually injected at energies higher than the transition energy.

18.3.6
Beam Injection and Extraction

A linac or microtron is usually used as a preaccelerator to inject particles into the synchrotron. In the first stage of the preaccelerator, ion sources or electron guns are used for the particle sources. Injection usually takes place at an energy of tens or hundreds of mega electronvolts. The field strength of the injection magnets is chosen so as to make the equilibrium orbit of the injection particle energy coincide with the central orbit of the synchrotron. The design aims of the injection system are to achieve transfers with little beam loss and with a minimum dilution of the beam emittances. The area of the region in phase space that can be used for injection of the accelerator is called the *acceptance*, which is determined by both the physical aperture (such as the width of the beam pipes) and the orbit parameters. In practice, errors in the magnetic fields and nonlinear oscillations cause a reduction of the acceptance (*dynamic aperture*).

Single-turn injection schemes are relatively straightforward (Figure 18.9). The beam is injected onto a central orbit through a septum unit and a fast kicker element with appropriate matching arranged in both the transverse and longitudinal planes. There should be no beam loss and very little emittance dilution. For the longitudinal plane, the momentum spread and phase parameters of the incoming bunch must be matched to those of the bucket defined by the rf fields of the ring.

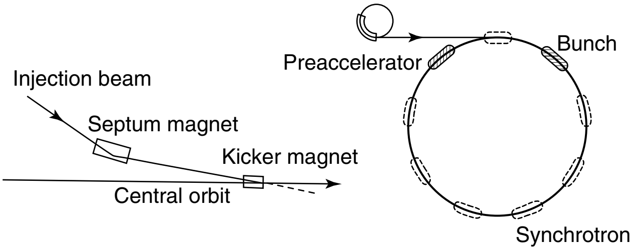

Fig. 18.9 Example of injection scheme.

In a *multi-turn injection,* the beam is injected for a period of time longer than the revolution time, thus stacking the beam in many turns. The process for electron accelerators is significantly different from that for proton or heavy-ion machines. The electron rings take advantage of *radiation-damping* effects to reduce the emittance of the beam. Proton and heavy-ion machines generally operate at a beam emittance that is set by space-charge effects. The hardware required for multiple-turn injection is not greatly different from that used for single-turn injection, but the role of the fast kicker is replaced by that of orbit bump magnets.

Proton machines have utilized a type of multiple-turn scheme known as *charge-exchange injection*, which requires micron or submicron stripping foils.

Particles in the synchrotron are most often extracted and led to the experimental areas outside the ring, or led to other machines, such as storage rings. *Fast extraction* is commonly used for beam transfer between synchrotrons and storage rings. Special kicker magnets remove individual bunches from the ring, or distort the beam orbit so that the entire beam can be extracted during a single turn.

There is also a *slow-extraction* process, requiring one to several seconds, and called *resonant extraction*. In this process, the dipole magnetic field is usually maintained constant. Then, the quadrupole magnets are tuned until the betatron oscillations are close to resonance. At the same time, a local perturbation field is applied, often using a sextupole magnet, and then varied slowly to sweep the beam through the resonance. During this sweep, particles are brought continuously into resonance, resulting in a controlled growth of the beam size. The extraction then takes place using a septum to scrape the beam.

18.3.7
Effects of Synchrotron Radiation

18.3.7.1 Radiation Damping and Quantum Fluctuation

The properties of synchrotron radiation can be derived by applying the methods of classical electrodynamics to the motion of relativistic charged particles in circular orbits. The theory of synchrotron radiation is based on the work of Iwanenko and Pomeranchuk (1944) as well as Schwinger (1946). Because of the relativistic speed of the particles, the angular distribution of the synchrotron radiation is strongly concentrated into a narrow cone in the instantaneous direction of motion. The spectrum extends from the microwave region to the hard X-ray range. The Lorentz transformation of the radiation pattern from the rest frame of the electron into the relativistically moving frame leads to a distribution of the intensity into higher energy.

The energy radiated in one revolution by a monoenergetic relativistic charged particle in a circular orbit (bending radius ρ) is expressed as

$$U_0 = \frac{e^2}{3\varepsilon_0}\frac{\beta^3\gamma^4}{\rho} \tag{19}$$

where $\beta = v/c$ and $\gamma = E/mc^2$. The total radiated power also depends on γ^4, which explains why electrons are used to produce synchrotron radiation. Electron machines require a large radius to obtain higher energies to keep the radiated power at a reasonable value. For example, the Large Electron Positron (LEP) collider at CERN was designed with a maximum energy of more than 100 GeV and a circumference of 27 km. It can also be seen that the emission of synchrotron radiation from protons is very small for energies up to several hundred giga electronvolts.

Synchrotron radiation is emitted primarily along the direction of motion into a narrow cone within an approximate angle of $1/\gamma$. The reaction force and the accompanying momentum change are opposite to the direction of motion. The only effect of the radiation is then to decrease the energy of the electron without changing its direction of motion. Energy losses are replaced by rf acceleration. As a consequence of the acceleration, the amplitudes of the synchrotron oscillation and the betatron oscillations are damped. The processes are known as *radiation damping* in electron machines.

Damping of the Energy Oscillations Small energy oscillations, synchrotron oscillations, are damped at a rate proportional to the change in the radiation loss with the energy. Since the energy loss per turn (U_0) due to synchrotron radiation depends on E^4, a particle having higher energy radiates more, and one having lower energy radiates less than the ideal particle. Therefore, in both cases the energy deviation tends to be reduced. The phase oscillation is also damped because of their conjugate relation. We assume that the amplitude decays as $\exp(-\lambda t)$, where λ is a damping coefficient approximately written as U_0/T_0E_0. (For rigorous discussions one should consult the literature – for example, Sands (1970).)

Damping of the Betatron Oscillations The emission of a photon implies a momentum loss in both the transverse and longitudinal directions. The transverse oscillations (vertical and horizontal betatron oscillations) are damped because the rf acceleration compensates for energy loss with an rf field in the longitudinal direction. The damping coefficients of the betatron oscillations in both the vertical and horizontal directions are approximately written as $U_0/2T_0E_0$.

Quantum Fluctuation and Beam Sizes Until now, we have considered only the total energy loss due to synchrotron radiation, assuming implicitly that the energy loss is a continuous process. However, all electromagnetic radiation occurs in quanta of discrete energy. This quantization of the energy loss has significant effects on the behavior of electron beams.

Each time a quantum is emitted, the energy of the electron makes a small discontinuous jump. This discontinuous energy change disturbs the trajectory of the electron (*quantum fluctuation* or *quantum* *excitation*). Such disturbances are a kind of random noise, which causes their amplitudes to grow until the quantum excitation is, on the average, balanced by radiation damping of the oscillations. The beam sizes in the transverse and longitudinal directions, beam emittances, and spread in energy are thus determined in an equilibrium state.

18.3.7.2 Quantum Lifetime

The transverse distributions of particles in a stored beam can be assumed to have a Gaussian form and, thus, a tail that extends to infinity. The beam is actually limited at least to the vacuum chamber, which causes particle loss. When the particle loss is small, the loss rate is proportional to the number of particles, N. Therefore, N decreases exponentially with a time constant τ_q according to

$$\frac{1}{\tau_q} = -\frac{1}{N}\frac{dN}{dt} \tag{20}$$

The constant τ_q is referred to as the *quantum lifetime* and, in an ideal case, is given as

$$\tau_g = \frac{\tau}{2}\frac{\exp\xi_q}{\xi_q} \tag{21}$$

where τ and ξ_q are given values for the transverse and longitudinal directions. The quantum lifetime, which depends on the transverse direction, is related to the betatron oscillations; τ is the damping time of the betatron oscillation (τ_x or τ_y), and

$$\xi_q = \frac{1}{2}\left(\frac{a}{\sigma}\right)^2 \tag{22}$$

where a is the aperture size and σ (σ_x or σ_y) is beam size in the horizontal or vertical direction, respectively.

A bunch loses particles through longitudinal motion in the rf bucket. The lifetime due to synchrotron oscillation is obtained by putting τ for the damping time of the synchrotron oscillation, and

$$\xi_q = \frac{1}{2}\left(\frac{E_m}{\sigma_E}\right)^2 \tag{23}$$

where E_m is the bucket height and σ_E the standard deviation in the particle energy.

18.4
Applications of Synchrotrons and Storage Rings

18.4.1
Synchrotrons and Storage Rings for Nuclear and for High-Energy Physics

For medium-energy or high-energy experiments, accelerated protons or heavy ions are most often extracted from a synchrotron and transported to the experimental stations. The beam particles bombard various fixed targets where interactions among particles are studied or where beams of secondary particles are generated. Secondary beams, such as antiprotons or radioactive ions are also guided to the experimental areas and are fed to fixed targets. Beams of neutrinos and muons, which are decay products of π-mesons, are also important tools for basic research.

At present, storage-ring colliders dominate the high-energy field. For particle–antiparticle collisions, one can use a single ring, where they circulate in opposite directions in the same magnetic guide field. For proton–proton collisions or electron–proton collisions, a double ring must be used. The largest colliders are the LHC at CERN, Tevatron at FNAL and Relativistic Heavy Ion Collider RHIC at BNL. The technologies of *beam cooling* were developed for such facilities and are now being applied in smaller storage rings. The large synchrotrons and storage-ring colliders presently in operation are listed in Table 18.1.

The development of heavy-ion accelerators is closely related to that of proton accelerators. Most heavy-ion accelerators, including cyclotrons, linacs, and electrostatic machines, are used to accelerate both protons and heavier nuclei. The acceleration principle of heavy-ion synchrotrons is exactly analogous to that of protons. However, since the velocity of ions is slow during injection, the frequency range of the rf system must be wide to maintain synchronous acceleration as the ion velocity increases. The beam-monitoring system must be very sensitive because of the low beam intensity. Since the charge state of stripped ions changes during collisions with the residual gas molecules in the beam pipe, which leads to a beam loss, an extremely good vacuum is required, typically 10^{-8}–10^{-10} Pa.

18.4.2
Applications of Synchrotrons and Storage Rings for Materials Science and Others

18.4.2.1 Neutron Sources for Materials Science

Relatively low-energy (0.5–1.5 GeV) proton synchrotrons with high currents and high repetition rates are useful as sources of intense neutron beams. Slow-neutron beams are excellent tools for studying condensed matter on account of their penetration ability due to the neutral charge.

Tab. 18.1 Proton and heavy-ion synchrotrons, storage rings and colliders for nuclear and for high-energy physics.

Accelerator	Institution[a]	Particles (energy)	Luminosity ($\text{cm}^{-2}\ \text{s}^{-1}$)	Particles/cycle	Remarks

Tab. 18.2 Operating proton synchrotrons and accumulator rings for pulsed spallation neutron sources.

Accelerator	Institution[a]	Particles (energy)	Cycle	Beam power	Remarks
ISIS	RAL	p (800 MeV)	50 Hz	160 kW	Rapid cycling synchrotron
SNS	ORNL	p (1 GeV)	60 Hz	1.4 MW (design)	Accumulator ring

[a] RAL: CCLRC Rutherford Appleton Laboratory, Chilton, UK. ORNL: Oak Ridge National Laboratory, TN, USA.

An extracted proton beam produces intense neutron bursts by spallation in a heavy-metal target. In such collisions, the created neutrons of rather high energy are emitted in the forward direction. However, most of the neutrons, having an energy peak at around 1 MeV, are almost uniformly distributed in angle. The velocities of such neutrons are slowed down by a moderator that surrounds the target. The slowed neutrons are called *cold neutrons* (0.1–10 MeV), thermal neutrons (5–100 MeV), and epithermal neutrons (100–500 MeV), respectively. Spallation neutrons form a pulsed beam of microsecond or submicrosecond duration having a high peak current. Such a time structure has a greatly different property compared to neutrons delivered from nuclear reactors, and is well used to investigate the time-varying nature of the materials. Examples of pulsed neutron sources are given in Table 18.2.

18.4.2.2 Synchrotron-Radiation Sources

Synchrotron radiation (see above) is one of the most valuable tools among the application fields of circular accelerators. Synchrotron radiation has been used for basic studies of materials science. Recently, applications are being widely and rapidly developed for chemical and biological research, as well as for industrial purposes. In the early stage, electron synchrotrons were used as sources for synchrotron-radiation research, which was a by-product of high-energy physics. At present, they are mostly being replaced by storage rings constructed as dedicated synchrotron-radiation sources.

Since the use of storage rings as synchrotron-radiation sources is spreading into various fields, a large number of storage rings have been constructed, or are under construction, worldwide. Electron storage rings of 1–2 GeV are built for using radiation from the vacuum-ultraviolet (VUV) to the soft X-ray range. For X-ray users, storage rings having energies of 2–8 GeV are constructed or under construction. Modern synchrotron-radiation sources include electron storage rings designed to circulate high-current beams with very low emittance to produce high-brightness radiation. The storage ring contains several or some tens of long straight sections for installing insertion devices, such as undulators or wigglers, whose periodic magnetic fields are designed to produce radiation with particular properties. Modern rings generally have large circumferences of several hundred meters up to more than one thousand meters.

Besides academic research, the application of synchrotron radiation has also spread to materials research and development in industry. Semiconductor

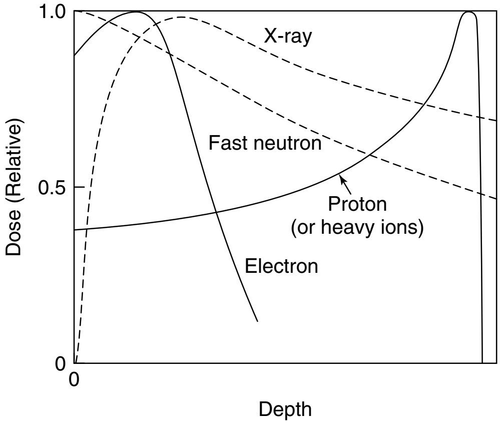

Fig. 18.10 Relative dose as a function of the depth in water for various types of beams.

lithography is being studied, which is going to realize semiconductors on the submicron scale for producing the next generation of microchips or microcircuit components. In addition to microelectronics technology, very fine fabrication to make tiny mechanical parts is under development using the technique of lithography. Small-size, low-cost machines, so-called compact storage rings, with energies usually below 1 GeV, are being built for industrial use. In the design of such machines, superconducting magnets are often used for the purpose of size reduction.

18.4.2.3 **Radiotherapy**

Heavy-ion synchrotrons as well as proton synchrotrons in the range of several hundred mega electronvolts are used for radiotherapy, such as cancer treatment. The aim of radiotherapy is to destroy the malignant cells with radiation beams. However, when radiation travels through the body, the normal tissues along the path are also damaged. Protons and heavy ions have well-defined particle ranges. The maximum energy is deposited in a region only a few millimeters in length near the end of range (known as the Bragg peak), as shown in Figure 18.10 This is an excellent property for radiation therapy, compared with X-ray, electron, or neutron beams. This allows a high dose to be delivered while concentrating on a diseased part with less damage to the overlying healthy tissues. Although the present status of this field is still experimental, dedicated facilities are under design or construction.

18.5
Technology and Engineering Aspects

18.5.1
Magnet System

The magnet is the most important and expensive item in circular accelerators. Various types of magnets are required, such as dipoles for bending the beam path and quadrupoles for focusing. Such magnets in synchrotrons are constructed under the requirements for a high degree of field quality and homogeneity over very large dimensions. For beam injection and extraction, they require kickers for the fast deflection of beams and septa for separation between the synchrotron chamber and the pipe for beam transport.

The progress of superconductivity technology has resulted in a new generation of magnet systems (see 18.5.6).

18.5.2
Radio-Frequency Engineering

Rf generators are needed to provide accelerating power for circulating beams and to compensate for the energy emitted as synchrotron radiation of the stored beams in the electron storage rings. In an electron storage ring having an energy of more than 1 GeV, several megawatts of rf power at 300–500 MHz are typically delivered to several rf cavities located in the ring. In this case, a UHF klystron of 100–1000 kW (continuous wave) is usually used as an rf generator.

In addition to the high-power systems, low-power rf technologies are very important because an accurate control of the frequency, voltage, and phase in the rf cavity is required for stable beam acceleration.

18.5.3
Computers and Automatic Controls

A large accelerator comprises a very complicated system, which contains a large number of components that must be controlled by computers. Such components are the rf accelerating system, the magnets and power supplies, the injection and extraction magnets, the vacuum system, the beam monitors, the timing circuits, the safety interlock system, and so on. Start-up, operation, and stopping of the entire machine system are in general automatically and finely controlled by computers.

Information concerning those machine components and beam parameters in the accelerators must be presented and displayed to the person who needs to interact with the machines. Practically, beams in accelerators are always changing their parameters, such as beam currents, beam positions, energies, and beam sizes. These parameters are always monitored during injection, acceleration, and extraction, and have to provide a feedback to the beams; otherwise, the machine would lose its stable operation. Such parameters of the beams and the current status of the machine components are recorded and displayed on screens. The control of the safety system is an important role of computers. It contains protection against radiation hazards, electricity accidents, and vacuum troubles.

18.5.4
High-Vacuum Engineering

The beam chambers of synchrotrons and storage rings require a vacuum of very low pressure over very large areas. Chambers are usually made of nonmagnetic metals (e.g., stainless steel, aluminum alloys, and copper), and insulation materials, such as ceramics, in special cases. Synchrotrons require a pressure in the range 10^{-5}–10^{-7} Pa to preserve the beam quality. A very low pressure of 10^{-7}–10^{-10} Pa is required for storage rings, and collider rings in which a beam must be stored for many hours, or even days, without any significant beam loss caused by scattering with residual gas molecules. The time in which the number of particles becomes half, or $1/e$, is called the *beam lifetime*. The beam lifetime is, roughly speaking, inversely proportional to the vacuum pressure in the beam chamber (the lifetime is often determined by reasons other than the finite vacuum pressure).

In electron (positron) storage rings, special techniques are used to achieve such low pressures in the presence of high-power synchrotron radiation hitting the chamber walls. Outgassing due to the photodesorption process results in difficulty in maintaining a sufficiently low pressure under operation of high-current electron beams. Special considerations are necessary for choosing the materials of the chambers and for methods of surface treatment to obtain a good vacuum.

The vacuum chambers of synchrotrons or storage rings require some special performance. The electromagnetic interaction between the beam-chamber walls and circulating beams becomes crucial when the beam current is large. Electromagnetic fields (wake fields) are generated inside the chamber by interactions of the beam charge with the conducting wall surface. The wake fields sometimes shake the beams, thus causing beam instabilities.

18.5.5
Civil Engineering

The magnets and other components of synchrotrons must be aligned at a tolerance level of 0.1 mm over a large extent. This tolerance level must be maintained for 10–20 years. The construction of the building in which the machine is to be installed thus carefully takes into account such factors as distortion due to thermal stress and the placement of heavy components, and vibration from utilities.

18.5.6
Superconducting System

The technologies of superconductivity are already widely utilized in accelerators, such as magnets and rf cavities. The development of superconducting magnets (see above) in accelerator applications started around 1970 with the first available multifilamentary composite material. The main advantage of using superconducting magnets is that they allow the field to be increased, so that the sizes of accelerators, and, therefore, the construction costs, can be considerably reduced. Since heating loss is very low, operating costs also decrease. The Tevatron at FNAL is the first superconducting accelerator, using NbTi as a superconductor in the 5-T range at 4.2 K.

The LHC (CERN) employs superconducting magnets and rf cavities. The LHC dipole magnets (1.9 K) have to produce a field of around 8.4 T. Each dipole magnet is 14.3 m long (see Figure 18.11). In total, there are 1232 dipole magnets in the ring.

Superconductive rf cavities, for example, with Nb as a superconductor, are widely used for saving electric power. The power

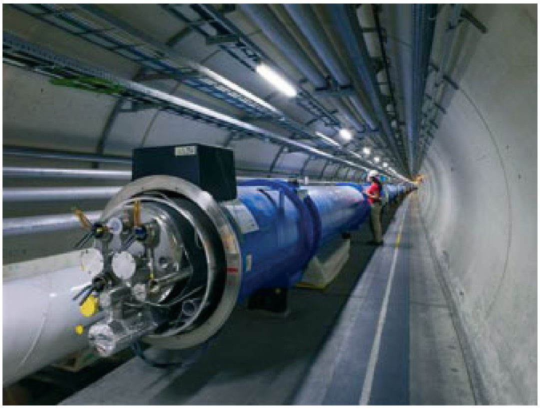

Fig. 18.11 LHC dipole magnet in its cryostat.

loss on the Nb cavity wall is $\frac{1}{10}$ of that on copper, and the accelerating voltage can be an order of magnitude larger than that of copper.

The storage rings for synchrotron-radiation sources built for industrial purposes widely use superconductive magnets for reducing their size and cost.

The superconducting systems in accelerators require sophisticated cryogenic systems. Technological progress in high-temperature superconductive materials is important and will influence future accelerator technologies.

Glossary

Beam Cooling: In storage rings, the beam emittances and momentum spreads are important parameters and are generally expected to be maintained at small values. The manipulation used to reduce the beam emittances and momentum spreads in accelerators is called *beam cooling*. The following methods have been developed: (i) radiation cooling for electron storage rings using radiation damping, (ii) electron cooling for ion beams, proposed by Budker (1966), and (iii) stochastic cooling using a feedback system (Van der Meer, 1972).

Beam Monitor: The equipment used to observe the beam intensities, beam positions, beam profiles, bunch lengths, and their variations in time are called *beam monitors*. The observation of the beam intensity commonly uses current transformers. The positions of the beams in the synchrotron are usually measured with pickup electrodes (e.g., bottom-type electrodes or strip-line electrodes).

Bunch: A bunch is defined as the group of particles formed due to the period of the rf accelerating field.

Luminosity: The performance of a storage ring for colliding-beam experiments is measured by the luminosity L, defined by $L = R/\sigma$, where R is the reaction rate, or number of interactions per second; σ is the interaction cross section. Typical values are in the range $L = 10^{29}$–$10^{32}\,\mathrm{cm}^{-2}\,\mathrm{s}^{-1}$.

Space-Charge Effect: When the beam intensity in a synchrotron is high, and particularly when the charged particles are tightly bunched and their velocities are slow, the Coulomb repulsion between them has two noticeable effects: (i) in the transverse direction, it counteracts the focusing forces of the synchrotron magnets. This results in shifts in the betatron tune. If the tune is drawn into a nearby resonance, a large loss of particles results. The shift in tune varies as $\beta^{-2}\gamma^{-3}$ (here, $\beta = v/c$, and $\gamma = E/mc^2$). (ii) In the longitudinal motion, it reduces the rf bucket area. A sufficiently high injection energy can cause the beams to be bound.)

INTRODUCTION

Synergetics and cybernetics are two interdisciplinary fields that deal with the behavior of systems in both the animate and the inanimate worlds. Largely based on mathematics, both fields have found widespread applications to physics, chemistry, electrical and mechanical engineering, biology, medicine, economics, psychology, and other disciplines. Roughly speaking, cybernetics focuses on the problem of how to control a system so that it shows a required behavior, while synergetics deals with self-organization of systems, where the various possibilities of new states of a system are studied that may occur when external but rather unspecific control parameters are changed. Both synergetics and cybernetics study deterministic and stochastic processes and their interplay.

This article elucidates both the overlap between these two fields and their distinctions. While in cybernetics negative feedback is in the foreground of interest, in synergetics both positive and negative feedbacks are studied. While in cybernetics the controlling agent is given from the outside, in synergetics the controlling agent in the form of order parameters (or informators) is generated by the cooperation of the individual parts of the system. Here the feedback loop is closed by the slaving principle. In cybernetics the problem of the stability of a system plays a major role. Synergetics focuses its attention on instabilities and qualitative changes of a system's behavior close to instability points. Nevertheless, as it will transpire, the transition between the two fields is rather smooth.

1. SYNERGETICS

1.1 Goals of Synergetics

Synergetics (S.) was initiated by Haken (1969) (see also Haken and Graham, 1971). It deals with systems that are composed of many individual parts (components) and that can spontaneously produce spatial, temporal, or functional structures by self-organization. "Self-organization" means that the specific structures are not prescribed from the outside by specific means. (Some examples are provided by Figs. 1–5.) S. searches for *general* (*unifying*) *principles of self-organization* irrespective of the nature of the parts of a system and establishes analogies between the macroscopic behavior of otherwise different systems. This is achieved by a mathematical description and the general concepts of stability, instability, control parameters, order parameters, and the slaving principle. S. has numerous applications in physics (including astrophysics, meteorology, and geology), chemistry, biology, computer science, psychology, economy, sociology, and other fields. In physics, chemistry, and biology, S. deals with open systems whose state is maintained by a flux of energy and/or matter into and out of the system under consideration. An example of a synergetic system is the light-source laser, whose principle may be described by the model of a gas laser. A glass tube is filled with a gas. The end faces of the tube carry mirrors that can reflect light running in the axial direction sufficiently often so that the damping of the light field is small enough and the laser condition can be met. The gas atoms are excited by an electrical current. In a usual lamp, the excited atoms emit individual wave trains of light entirely independently of each other so that microscopically chaotic light is produced. When the electric current is increased beyond a critical value, *coherent* light is emitted, i.e., a qualitatively new (highly ordered) state of the light field emerges. The coherence of laser light is brought about by the stimulated emission of radiation by the atoms. (Note the acronym "laser": light amplification by stimulated emission of radiation.)

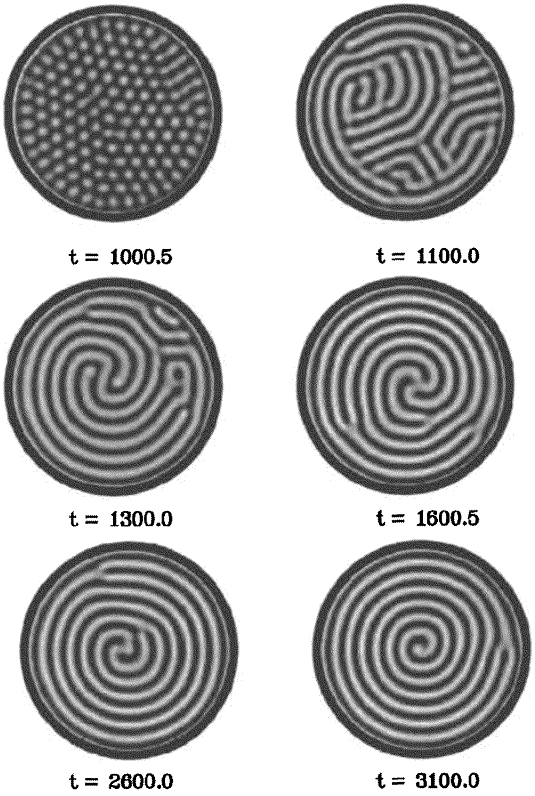

FIG. 2. Computer simulation of the transition from a hexagonal pattern to a spiral pattern in a liquid that is heated from below and cooled from above. This transition occurs when the walls are also heated (after Bestehorn *et al.*, 1993).

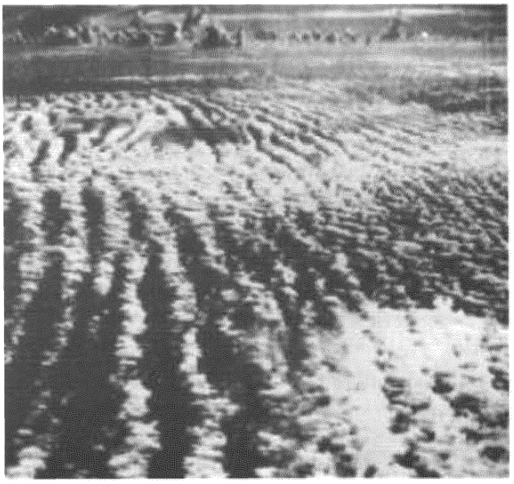

FIG. 1. Formation of cloud streets. These patterns are dynamic in that the air rises and sinks down spatially periodically (after Scorer, 1972).

The theoretical treatment of self-organiz-

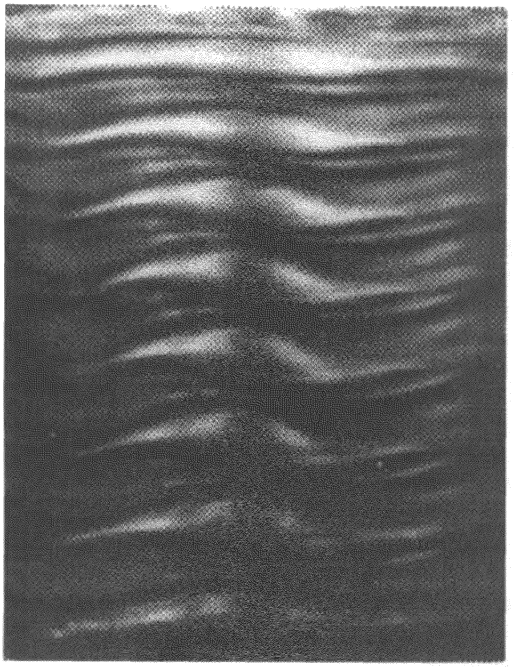

FIG. 3. Formation of periodic vortices in the so-called Taylor instability. A fluid is kept between two concentric cylinders of which the outer rotates. When the rotation speed exceeds a critical value, the patterns shown are formed. With increasing rotation speed, the patterns can become more complicated. For instance the pattern of Fig. 4 results (Swinney *et al.*, 1977).

ing systems distinguishes between microscopic (or mesoscopic), macroscopic, and phenomenological approaches.

1.2 Basic Concepts of Mathematical Treatment

1.2.1 Microscopic or Mesoscopic Approach Since the systems are open, their coupling to reservoirs (heat baths) must be taken into account. In the usual treatment, in a first step the reservoir variables are eliminated from the equations of motion, which may be classical or quantum mechanical. The resulting equations (see below) contain both damping of the system variables and fluctuations. The state, i.e., the spatiotemporal structure of a system, is represented by the—in general, time-dependent—state vector

$$\mathbf{q}(t) = (q_1, \ldots, q_n) \tag{1}$$

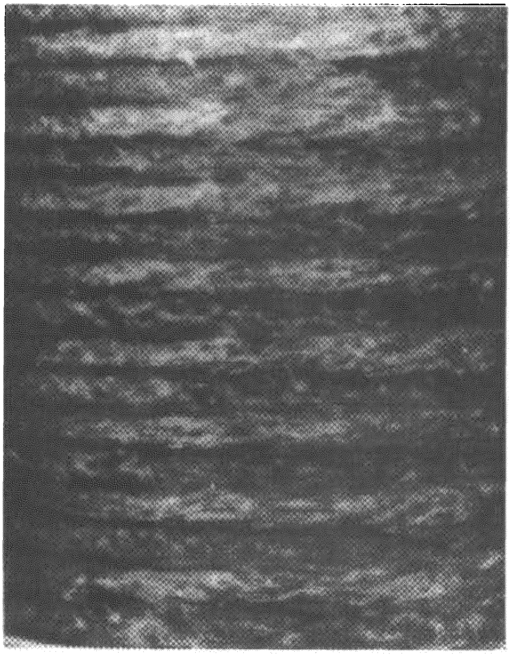

FIG. 4. Taylor instability leading to weak turbulence (Swinney *et al.*, 1977).

with its components q_j, $j = 1, \ldots, n$. Examples for these components in microscopic laser theory and nonlinear optics are atomic dipole moments, atomic inversion, and amplitudes of the modes of the electric-field strength. These quantities are classical variables in semiclassical theory and operators in quantum theory.

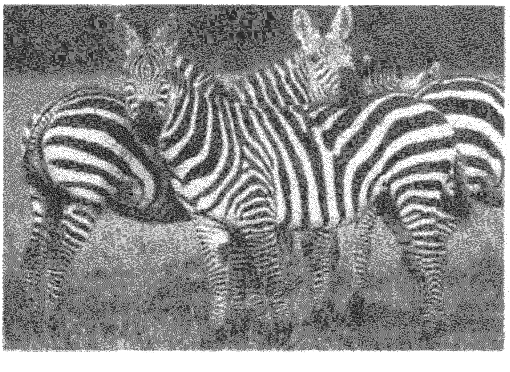

FIG. 5. A simple example of pattern formation in biology: formation of stripes on zebras. Such patterns can be accounted for by reaction-diffusion models based on the Turing instability (Turing, 1952; see also Meinhardt, 1982).

1.2.2 Mesoscopic Approach Here, a fluid is not described by the motion of its individual molecules but by the densities of its molecules, the velocity field, and the temperature field. In this case, the components of (1) become both space and time dependent. In plasmas the components of (1) are densities and velocity fields of electrons and ions, electric and magnetic fields, and temperature fields (see PLASMA PHYSICS; PLASMA WAVES AND INSTABILITIES). In semiconductors (1) refers to densities of electrons and holes, to occupation numbers of donors and acceptors, and to electric and magnetic fields.

In classical physics, chemical kinetics, a number of biological model systems, and other fields, **q** obeys evolution equations of the form (Haken, 1987)

$$\dot{\mathbf{q}} = \mathbf{N}(\mathbf{q},\nabla,\alpha,\mathbf{x}) + \mathbf{F}(t), \text{ where } \frac{d\mathbf{q}}{dt} \equiv \dot{\mathbf{q}}. \tag{2}$$

N is a *nonlinear* function of **q**. It may depend on spatial derivatives of **q** and may contain nonlocal couplings between the individual components of **q**. **N** depends on fixed control parameters α, which describe the influence of the surrounding "reservoirs" on the system, and it may explicitly depend on the space coordinate **x**. **F** represents fluctuating forces that may be caused from internal or external fluctuations (for instance, by coupling to the reservoirs). If **F** depends on the state variable **q**, the Îto or Stratonovich calculus (see Haken, 1987) must be used. In (2) it is assumed that $\dot{\mathbf{q}}$ and **q** refer to the same time. However, delay equations of the form

$$\dot{\mathbf{q}}(t) = \mathbf{N}(\mathbf{q}(t - T)) \tag{3}$$

or, more generally, of the form

$$\dot{\mathbf{q}}(t) = \mathbf{N}(\mathbf{q}(\tau)), \quad -\infty < \tau \leq t, \tag{4}$$

are also considered. In quantum theory, (2) is replaced by Heisenberg equations for operators **q**,

$$\dot{\mathbf{q}} = \frac{i}{\hbar}[H,\mathbf{q}] + \mathbf{R}(\mathbf{q}), \tag{5}$$

where H is the Hamiltonian of the system under consideration and **R** represents the effect of the (eliminated) reservoir variables. Alternative but equivalent descriptions of the system's evolution are the Fokker–Planck equation instead of (2) (for an example see below) and the density-matrix equation instead of (5).

1.2.3 Order-Parameter Equations and Slaving Principle Equations (2)–(5) are too general to be treated from a unifying point of view with results that are explicit enough for practical use. However, in many practical applications, the following strategy that is suggested by the laser example has proved highly successful. Assume that for a control parameter value α_0 a solution of (2) is known,

$$\alpha_0\colon \mathbf{q}_0(\mathbf{x},t). \tag{6}$$

$\mathbf{q}_0$ may be time independent, time periodic, time quasiperiodic, or chaotic. When the control parameter α_0 is changed, $\alpha_0 \to \alpha$, a linear stability analysis is performed, where the hypothesis

$$\mathbf{q}(\mathbf{x},t) = \mathbf{q}_0(\mathbf{x},t) + \mathbf{w}(\mathbf{x},t) \tag{7}$$

is made. Inserting (7) into (2), neglecting the fluctuating forces, and linearizing the resulting equation with respect to **w** leads to

$$\dot{\mathbf{w}} = L\mathbf{w}, \tag{8}$$

where L is a linear operator. The solutions of (8) have the general form

$$\mathbf{w} = \exp(\lambda_j t)\mathbf{v}_j(\mathbf{x},t), \tag{9}$$

where j is an index that distinguishes the different solutions of (8). If $\mathbf{q}_0$ is time independent, $\mathbf{v}_j$ is time independent or may contain powers of time t in case of degeneracies. If $\mathbf{q}_0$ is periodic, $\mathbf{v}_j$ is periodic and may contain powers of t in case of degeneracies. If $\mathbf{q}_0$ is quasiperiodic or chaotic, in large classes of systems $\mathbf{v}_j$ is also quasiperiodic or chaotic. In the case that (6) is time independent, the solution of (2) may be represented in the form

$$\mathbf{q}(\mathbf{x},t) = \mathbf{q}_0(\mathbf{x},t) + \sum_j \xi_j(t)\mathbf{v}_j(\mathbf{x},t). \tag{10}$$

(For the general case see Haken, 1987.) Inserting (10) into (2), and projecting on the

$\mathbf{v}_j$'s, Eqs. (2) may be cast into the general form

$$\dot{\xi}_j = \lambda_j\xi_j + \sum_{l,m} A_{jlm}\xi_l\xi_m + \sum_{l,m,n} B_{jlmn}\xi_l\xi_m\xi_n + \cdots + \hat{F}_j(t), \tag{11}$$

provided **N** can be expanded into a power series in **q**. Depending on the size of the real part of λ_j, unstable and stable mode amplitudes ξ_u and ξ_s, respectively, may be distinguished:

$$\xi_u\text{: } \mathrm{Re}\lambda_u \geq 0, \tag{12}$$

$$\xi_s\text{: } \mathrm{Re}\lambda_s < 0. \tag{13}$$

The *slaving principle* of synergetics (Haken, 1987) states that the stable mode amplitudes ξ_s can be uniquely expressed by the unstable mode amplitudes ξ_u at the same time to any desired degree of accuracy provided $|\boldsymbol{\xi}_u|$ is small enough:

$$\xi_s(t) = f_s(\boldsymbol{\xi}_u,(t),t). \tag{14}$$

In general, f_s can be approximated by a low-order polynomial for the components of $\boldsymbol{\xi}_u$. The explicit time dependence of $f_s(\boldsymbol{\xi}_u,t)$ stems from the time dependence of the fluctuating forces. By means of (10) and (14), $\mathbf{q}(\mathbf{x},t)$ can be expressed by the *order parameters* ξ_u alone. Since in general the number of $\boldsymbol{\xi}_u$ is much smaller than the number of the stable mode amplitudes ξ_s, the number of degrees of freedom of the system is greatly reduced and an enormous information compression achieved. Furthermore, in many practical applications it is sufficient to confine the sum over j in (10) to that over the order parameters ("mode skeleton"). The slaving principle contains a number of mathematical theorems or procedures as special cases. The adiabatic elimination procedure is based on the assumption that the λ_j's in (11) are real (or that by suitable transformations the imaginary part has been transformed away) and that $|\lambda_u| \ll |\lambda_s|$. (The fluctuating forces are neglected.) Then Eqs. (11) are split into those for $j = u$ ("unstable") and $j = s$ ("stable"). The *adiabatic approximation* means that in the equations for ξ_s, the assumption

$$\dot{\xi}_s \approx 0 \tag{15}$$

is made, by which these differential equations are converted into algebraic equations that can be solved by conventional means so that (14) can be established. In the *center manifold theorem* (Pliss, 1964; Kelley, 1967), it is assumed that $\lambda_u = 0$ and that there are no fluctuations. A further method of elimination of mode amplitudes ξ_s is by means of scaling procedures in which a specific scaling behavior of space, time, ξ_u, and ξ_s must be anticipated (see for instance Cross and Hohenberg, 1993).

By means of (14) the amplitudes ξ_s can be eliminated from Eqs. (11) so that order-parameter equations of the general form

$$\dot{\boldsymbol{\xi}}_u = \hat{\mathbf{N}}(\boldsymbol{\xi}_u,\alpha) + \hat{\mathbf{F}}(\boldsymbol{\xi}_u,t) \tag{16}$$

result. In a number of cases (16) can be simplified by use of normal-form theory (Arnold, 1983, 1993) and group theory (Sattinger, 1980) that exploits symmetry properties of the system.

If the spectrum λ_u of the linear operator L in (8) is continuous, the order parameters ξ_u become slowly space dependent,

$$\xi_u(t) \rightarrow \xi_u(\mathbf{x},t). \tag{17}$$

In this case the eigenvalues λ_u are transformed into operators, $\lambda_u(\partial/\partial x,\partial/\partial y,\partial/\partial z)$, that act on the space coordinate **x**, and Eqs. (16) acquire the form (Haken, 1987)

$$\dot{\boldsymbol{\xi}}_u = \lambda_u(\nabla)\boldsymbol{\xi}_u + \sum_{u',u''}\int dV'dV''A_{uu'u''}(\mathbf{x},\mathbf{x}',\mathbf{x}'')\,\xi_{u'}(\mathbf{x}')\xi_{u''}(\mathbf{x}'') + \cdots + \mathbf{F}(\mathbf{x},t). \tag{18}$$

Equations (18) are called *generalized Ginzburg–Landau* equations. Among special cases are the Swift–Hohenberg–Haken equation of the form

$$\dot{\boldsymbol{\Psi}}(\mathbf{x},t) = (\alpha + \beta(1 + \Delta)^2) + a\boldsymbol{\Psi}^2 - b\boldsymbol{\Psi}^3, \tag{19}$$

the original Swift–Hohenberg equation (Swift and Hohenberg, 1977) in which the quadratic term is lacking, and the nonlinear Schrödinger equation. The analogies between the behavior of different systems become manifest through Eqs. (16) or (18) with their special cases and the mode skeleton of (10). For instance the single-mode laser, a liquid developing a roll pattern, and a chemical reaction showing a stripe pattern have the same order-parameter equation.

1.3 Nonequilibrium Phase Transitions

Equations (16) and (18) may be considered as *generalized Langevin equations* to which the corresponding Fokker–Planck equation may be established (see Risken, 1989; Gardiner, 1983). Explicit examples of (16) and its corresponding Fokker–Planck equation are provided by

$$\dot{\xi}_u = \alpha\xi_u + \beta\xi_u^2 - \gamma\xi_u^3 + F(t) \qquad (20)$$

and

$$\dot{f}(\xi_u,t) = -\frac{\partial}{\partial\xi_u}[(\alpha\xi_u + \beta\xi_u^2 - \gamma\xi_u^3)f] + \frac{Q}{2}\frac{\partial^2 f}{\partial\xi_u^2}, \qquad (21)$$

respectively. Here f is the distribution function and Q is the strength of the fluctuating forces defined by

$$\langle F(t)F(t')\rangle = Q\delta(t - t'). \qquad (22)$$

The fluctuating forces are assumed to be white noise and Gaussian distributed with

$$\langle F(t)\rangle = 0. \qquad (23)$$

Examples for (20) and (21) (with $\beta = 0$) are provided by the order-parameter equations of a single-mode laser, of the convection instability with a single-roll pattern, and of stripe formation in some chemical reactions.

The behavior of ξ_u may be visualized by means of a ball sliding down in a potential as depicted in Fig. 6 (for the case $\beta = 0$) and subject to fluctuating forces. Close to $\alpha = 0$ *critical fluctuations* and *critical slowing down* occur. The occurrence of a *symmetry-breaking instability* is visible from Fig. 6. The stationary solution of (21) reads

$$f(\xi_u) = N\exp\left[\frac{2}{Q}\left(\frac{\alpha}{2}\xi_u^2 + \frac{\beta}{3}\xi_u^3 - \frac{\gamma}{4}\xi_u^4\right)\right] \qquad (24)$$

and puts in evidence the analogy between the behavior of a nonequilibrium system close to its instability point $\alpha = 0$ with the Landau theory of phase transitions. Equations (20), (21), and (24) describe a second-order *nonequilibrium phase transition* for $\beta = 0$, and a first-order nonequilibrium phase transition for $\beta \neq 0$ with hysteresis effect. In both cases, i.e., equilibrium and nonequilibrium phase transition, ξ_u serves as the order parameter, but while in the Landau theory the phase transition (Landau and Lifshitz, 1959) is caused by the temperature dependence of α, in the case of nonequilibrium systems α depends on rate constants. Note that in the case of a discrete spectrum of L, (20) and (21) are appropriate representations, and the Wilson theory of phase transitions of systems in thermal equilibrium (see PHASE TRANSITIONS: RENORMALIZATION AND SCALING) is not needed here.

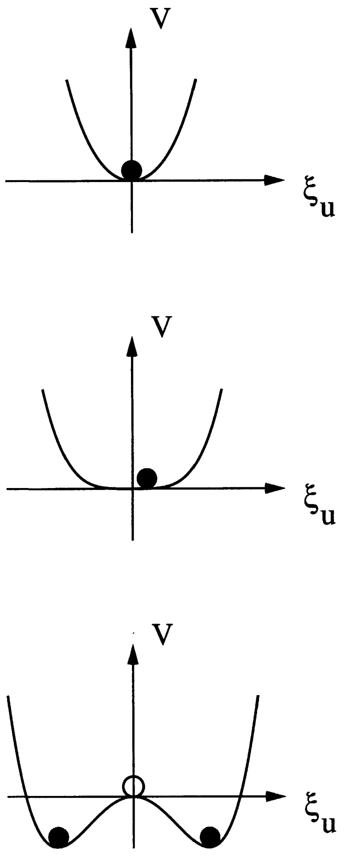

FIG. 6. Visualization of the solution of the order-parameter equation (20) with $\beta = 0$ by means of a ball sliding down the potential landscape $V = -(\alpha/2)\xi_u^2 + (\gamma/4)\xi_u^4$ for $\alpha < 0$ (upper part), $\alpha = 0$ (middle part), $\alpha > 0$ (lower part).

1.4 Instabilities and Instability Hierarchies

When fluctuating forces in (16) are neglected, concepts and results of dynamic systems theory (see Arnold, 1993; Guckenheimer and Holmes, 1993) may be invoked, and solutions of the order-parameter equations (16) may be classified as fixed points (time-independent ξ_u), limit cycles (time-periodic ξ_u), tori (time-quasiperiodic ξ_u), and chaotic ξ_u. If these objects are stable, they are called *attractors.* The region in phase space surrounding the attractor from which the trajectories are pulled into the attractor is called *basin of attraction.* When one or several control parameters are changed, the type of a solution of (2) or (16) may change. For instance, one stable fixed point may be replaced by an unstable and two stable fixed points (compare Fig. 6), or by a limit cycle that can be replaced by a torus or chaotic attractor, and so on. These transitions are studied by bifurcation theory and synergetics. A few phenomena that were derived from the solutions of equations (16) or (18) are the following: From Eqs. (16), lasers: cw single-mode operation, multiple-mode operation including steady states, frequency locking, ultrashort pulses, and chaotic laser light (Haken, 1985; Weiss and Klische, 1984). From Eqs. (18), transverse spatial and spatiotemporal patterns of the near and the far field of lasers and nonlinear optical devices (Arecchi and Harrison, 1987); in semiconductors current oscillations by impact ionization, current filaments (Schöll, 1987), Gunn oscillations, and chaotic oscillations.

In fluids, plasmas, and chemical reactions, spatio-temporal patterns can be treated via (16), (18), or (19). The patterns may depend on geometry (for instance, plane, square, or circular layers) or spherical geometry (such as in astrophysics, meteorology, or geophysics), and on initial conditions, fluctuations, intrinsic mechanisms, or driving conditions (e.g., heating from below). Among the patterns treated are rolls, hexagons, zigzag waves, single- and multiple-armed spirals, period-doubling routes to chaos, solitary waves, and defect structures.

1.5 Phenomenological Synergetics

In a number of cases, such as in complex physical or chemical systems, and in particular in biology, the behavior of the microscopic parts is not directly accessible to a mathematical description. Nevertheless, in a number of cases it is possible to describe the behavior of the system phenomenologically by an appropriate identification of control and order parameters. In this case, Eqs. (16) or (18) are formulated heuristically. Examples are provided by fluid dynamics (for instance, Ginzburg–Landau equations and some generalizations) or in biology by models of movement coordination (Haken *et al.*, 1985), Eigen equations of evolution (Eigen, 1971), Gierer–Meinhardt model of morphogenesis (see Meinhardt, 1982), etc.

1.6 Macroscopic Synergetics

The aim is to derive underlying equations of motion for the order parameters or even for enslaved mode amplitudes using the available experimental data. In the Friedrich–Uhl–Haken method (Friedrich *et al.*, 1995a,b), the leading terms of both the order-parameter equations (16) and the slaving principle (14) are taken into account, and the unknown coefficients that appear in (14) and (16) are determined by a least-squares fit where the experimental data enter. A further approach is based on the maximum-information entropy principle (Jaynes, 1957a,b, 1962) that can be formulated as follows: Let p_j be the probability of finding a system in state j, $j = 1, \dots, M$, and set $K = 1/\ln 2$. Then the information—or information entropy—

$$i = -K \sum_j p_j \ln p_j \tag{25}$$

is maximized by an appropriate choice of the p_j's under the constraints

$$\sum_j p_j = 1 \tag{26}$$

and

$$\langle f^{(k)} \rangle \equiv \sum_j f_j^{(k)} p_j = f_k. \tag{27}$$

While the $f_j^{(k)}$'s are given functions, the f_k's are experimentally observed average values. In most applications to synergetics, the index j is identified with the (continuous) state vector $\mathbf{q}$, Eq. (1), and the constraints (27) to be used are moments of the components of $\mathbf{q}$ mostly up to the fourth order of the form

$$\langle q_k \rangle = \bar{q}_k, \langle q_k q_{k'} \rangle = \overline{q_k q_{k'}}, \cdots. \tag{28}$$

While the left-hand sides of Eqs. (28) are defined according to (27), the right-hand sides are averages over experimentally observed time series of moments, i.e., of products of q_k, as indicated by the bars. Maximizing (25) under the constraints (26) and (27) yields

$$P(\mathbf{q}) = N \exp\left\{-\sum_j \lambda_j q_j - \sum_{jj'} \lambda_{jj'} q_j q_{j'} \cdots\right\} \tag{29}$$

for the time-independent distribution function. Note the analogy with (24). Also, time-dependent processes can be analyzed using the maximum-information entropy principle provided the process is Markovian (Haken, 1988). Based on conditional moments, the short-time propagator is thus determined.

1.7 The Synergetic Computer

The synergetic computer (Haken, 1990) represents an alternative to neural computers [see NEURAL NETWORKS including spin-glass models (Hopfield, 1982)]. It is used, in particular, for pattern recognition in the form of an associative memory (Kohonen, 1987) and based on the idea that pattern recognition can be considered as pattern formation. The prototype patterns to be stored are encoded as vectors

$$\mathbf{v} = (v_1, \cdots, v_j, \cdots, v_N), \tag{30}$$

whose components may be, for instance, the gray values of the corresponding pixels of a picture. The prototype vectors are distinguished by the index k:

$$\mathbf{v}_k, \quad k = 1, \cdots, M. \tag{31}$$

They are assumed to be normalized,

$$\mathbf{v}_k^2 = 1. \tag{32}$$

The adjoint vectors $\mathbf{v}_{k'}^{\dagger}$ obey

$$\mathbf{v}_{k'}^{\dagger} \cdot \mathbf{v}_k = \delta_{kk'}, \tag{33}$$

where δ is the Kronecker symbol. The synergetic computer uses a dynamics in which an offered test pattern vector $\mathbf{q}$ becomes time dependent and is, eventually, identified with one of the stored prototype patterns to which it had been most similar in the beginning:

$$\mathbf{q} \rightarrow \mathbf{q}(t) \rightarrow \mathbf{v}_k. \tag{34}$$

This dynamics is described by the equations

$$\dot{\mathbf{q}} = \sum_k \lambda_k (\mathbf{v}_k^{\dagger} \mathbf{q}) \mathbf{v}_k - \sum_{kk'} B_{kk'} (\mathbf{v}_{k'}^{\dagger} \mathbf{q})^2 (\mathbf{v}_k^{\dagger} q_k) \mathbf{v}_k - C \mathbf{q}^2 \mathbf{q}. \tag{35}$$

Equations (35) can be derived from a potential function V

$$\dot{\mathbf{q}} = -\frac{\partial V}{\partial \mathbf{q}^{\dagger}}. \tag{36}$$

Examples of prototype patterns $\mathbf{v}_k$ stored in the computer and the recognition process are shown in Figs. 7 and 8. A learning algorithm (Haken *et al.*, 1989) allows the synergetic computer to learn the prototype patterns even if the offered patterns are noisy or partly hidden (Fig. 9), or if classifications must be made. To this end, the potential function

$$V_{\text{tot}} = \sum_j V(\mathbf{q}_j, \mathbf{v}_k, \mathbf{v}_k^{\dagger}), \tag{37}$$

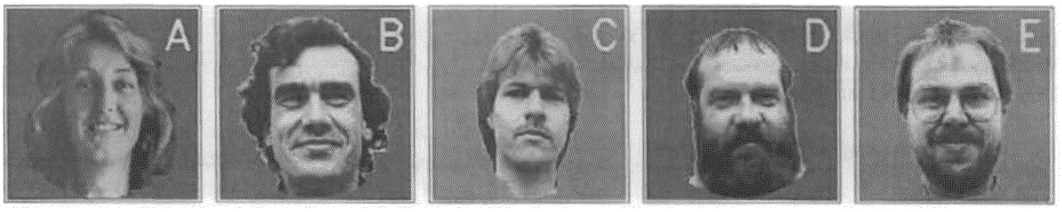

FIG. 7. Examples of stored prototype patterns including the encoded family names.

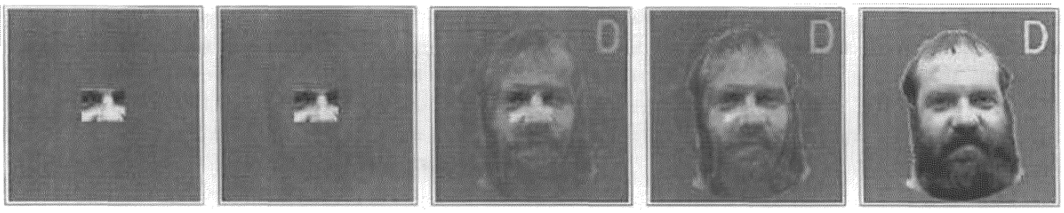

FIG. 8. Example of a recognition process, where part of a face is prescribed as initial state.

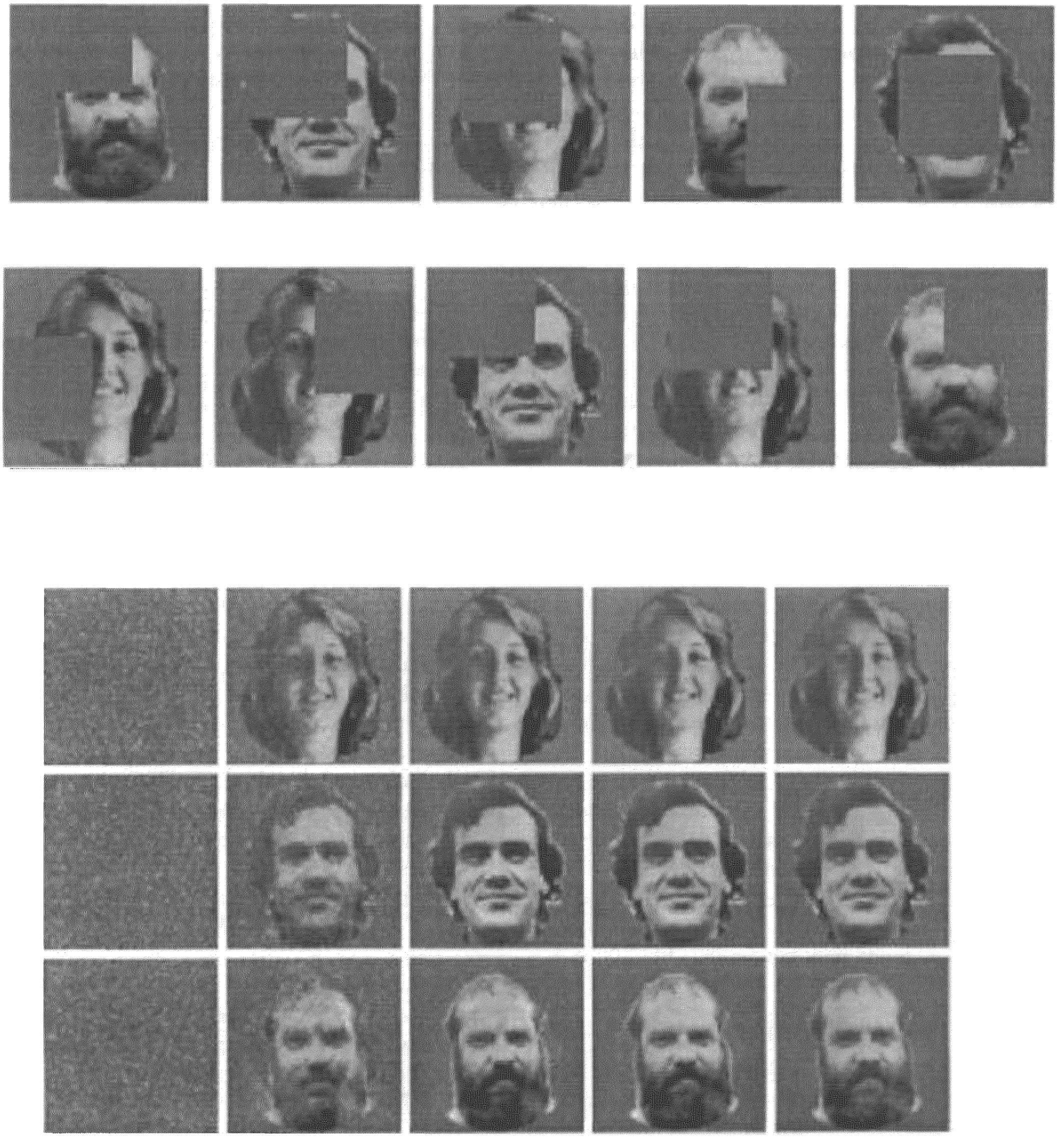

FIG. 9. Learning of partly hidden faces. Upper part: A random sequence of such patterns, each time with a different position of the squares, was offered to the computer. Lower part: Simultaneous learning of the three offered faces.

where the sum runs over all offered patterns, is minimized with respect to $\mathbf{v}_k$ and $\mathbf{v}_k^\dagger$ by a gradient dynamics, where the constraints (32) and (33) are taken into account. The sum in (37) runs over all patterns offered to the computer.

1.8 Some Further Applications

In chemistry synergetics is applied to pattern formation in the Belousov–Zhabotinski reaction and other reactions (for reviews see Ross *et al.*, 1988; Nicolis, 1989). In that chemical reaction $Ce_2(SO_4)_3$, $KBrO_3$, $CH_2(COOH)_2$, H_2SO_4 and a few drops of Ferroin (redox indicator) are mixed. The thus resulting homogeneous mixture can show oscillations or develops spirals or concentric rings depending on the geometry of the vessel (and on the continuation of stirring in the case of oscillations).

In biology and medicine, synergetics applies to the Turing model of morphogenesis (Turing, 1952). This model proposes a mechanism of cell differentiation during the development of an organism. In its original form the model considers two undifferentiated cells (for instance, of an embryo in its early stage). In both cells the same chemical reactions (metabolisms) are going on. When an exchange of molecules between the cells is permitted, a small fluctuation of the concentration of one kind of molecules can cause an instability whereby the concentrations of molecules change and become dramatically different in the two cells. It is assumed that high concentrations of so-called activator molecules can switch on genes, which leads to cell differentiation, for instance, to the production of pigments on furs, or to specific cells of organs. The Turing model was extended to sheets (or other ensembles) of cells by Gierer, Meinhardt, and others (see Meinhardt, 1982). Stripe and hexagonal ("spot") patterns on furs or on skins of fish were derived from this model by Olbrich and Haken (see Haken, 1983) by use of the concepts of synergetics.

Models of evolution of biomolecules (Eigen, 1971; Eigen and Schuster, 1977, 1978) utilize synergetics. These models deal with the early stage of the evolution of life at the level of biomolecules. It is assumed that these molecules (probably RNA) can multiply, mutate, and compete with each other. Because of a specific fitness factor, one kind of molecule ("species") wins the competition so that selection is achieved. There is a one-to-one correspondence between the original Eigen equations and the photon-number equations of the laser so that the evolution dynamics can be mimicked by the latter.

Synergetics applies to movement coordination in humans and animals (Kelso, 1995; Haken, 1996). The movement of limbs is highly correlated and shows up in specific movement patterns ("gaits"). The concepts of synergetics allow one to model mathematically the transitions between movement patterns. A classical experiment is that by Kelso (1995), where a person is asked to move the index fingers of both hands in parallel. When the frequency of the movement is enhanced, suddenly and involuntarily a switch to an antiparallel, symmetric movement pattern occurs. The movement frequency plays the role of a control parameter and the relative phase that of an order parameter. Phenomena such as hysteresis, critical fluctuations, and critical slowing down could be predicted. The phenomena described by this model seem to be of a universal nature in movement coordination.

Synergetics may enter into the analysis of electroencephalograms (EEGs) and magnetoencephalograms (MEGs) (Haken, 1996). In EEGs (MEGs) the spatio-temporal distribution of electric (magnetic) fields over the scalp is measured. It is assumed that hereby the electric (magnetic) activity of the brain is measured. If it is assumed that the brain operates close to instability points, the concepts of synergetics as outlined in this article become applicable. The observed spatiotemporal (EEG or MEG) patterns can be decomposed into a superposition of a few spatial modes with time-dependent amplitudes that act as order parameters and obey typical order-parameter equations. Examples are the analysis of α-waves (with five order parameters), petit-mal epilepsy (with three order parameters that show so-called Shilnikov chaos), or MEGs in sensorimotor control tasks, such as finger tapping on acoustic signals (with two order parameters).

Models of perception [including that of ambiguous figures (Haken, 1996)] are based on the synergetic computer (see Sec. 1.7) but take into account the time dependence of the so-called attention parameters λ_k that occur in (35). This time dependence is caused by the saturation of attention and leads to an oscillation between different percepts associated with ambiguous figures. Qualitatively, perhaps in a more speculative fashion, synergetic concepts were applied to psychology, psychiatry, and group therapy (see, for instance, Langthaler and Schiepek, 1995).

In sociology, synergetics is applied to formation of public opinion (Weidlich and Haag, 1983). The numbers of persons with specific political opinions serve as order parameters that obey typical order-parameter equations. As a consequence of changes of specific control parameters (e.g., political "climate"), dramatic changes of public opinion can occur. Transitions between democratic behavior and dictatorship become accessible to mathematical modeling. For more intricate situations and their models, see Weidlich and Haag (1983).

In urban development (Sanders, 1992), in studies related to synergetics, the development of cities is conceived as a process of self-organization. Among basic questions is this: How can planning agencies fix appropriate control parameters that allow for self-organization of cities into desired structures?

In models of economy (Zhang, 1991), questions treated are these: How can an economy be described (modeled) by a few characteristic quantities (order parameters)? What is their dynamics depending on specific control parameters (e.g., interest rates, oil price, etc.), and what typical changes can occur (e.g., transitions between full employment and underemployment)? Somewhat related problems occur in ecology—for instance, the impact of pollution on vegetation.

1.9 Relations to Other Fields and Limitations

Cybernetics (cf. Sec. 2): While in cybernetics the concepts of control, steering, regulations, etc. are in the foreground of interest, in synergetics the impact of unspecific changes of control parameters on the system's dynamics is studied. Synergetics shares the goal of general systems theory (founded by von Bertalanffi: von Bertalanffi, 1950, 1953) in that it looks for analogies in the behavior of different systems. While general systems theory looks for such analogies at the level of the individual parts, synergetics establishes such analogies at the level of the order-parameter equations (16) or (18). In this way, for instance, analogies between phenomena (chaos, spatiotemporal patterns) in fluid dynamics and lasers (Haken, 1985) were established. Relationships between synergetics and the theory of phase transitions of systems in thermal equilibrium were mentioned above.

S. shares a goal with the concept of dissipative structures in the sense of Prigogine (Glansdorff and Prigogine, 1971), in that it looks for general principles underlying self-organization. Principles proposed by the latter theory, namely, the principles of minimum entropy production and of excess entropy production, were not successful, however. Later work by the Prigogine school is mainly based on bifurcation theory (Nicolis and Prigogine, 1977; Nicolis, 1989). Dynamic systems theory including bifurcation theory (Guckenheimer and Holmes, 1993), catastrophe theory (*q.v.*; see also Thom, 1975), and chaos theory (Schuster, 1988; CHAOTIC PHENOMENA) provide synergetics with important mathematical tools, though, on the other hand, these theories ignore entirely the role of fluctuations and the statistical aspects that play a fundamental role in phase transitions far away from thermal equilibrium. Finally, information theory plays a role in synergetics via the concept of maximum information entropy. An interesting future task will be to establish profound links between fractal geometry (Mandelbrot, 1983; FRACTAL GEOMETRY), which is a static theory, and synergetics, which is a dynamic theory.

In its present form the mathematical approach outlined above applies to situations close to instability points (in control-parameter space), where the order parameters change smoothly. There are both experimental and theoretical indications that in a number of cases the order-parameter concept and the slaving principle are also valid away from the instability points. A phenomenon that has not (yet?) been accessible to these methods is turbulence. The same may be true for cases in which several or many instabilities coincide or follow closely (for instance, in plasmas).

2. CYBERNETICS

Modern cybernetics was introduced by Norbert Wiener as the science of control and communication in the animal, the machine, and even societies. Negative feedback, quantity of information, isomorphism, and requisite variety are among the important concepts of cybernetics. Perception and action are linked to cybernetics, which is close to systems theory and synergetics. Applications of cybernetics include robotics and information theory and may also be found in biological modeling, economics, and ecology.

2.1 Historical Background

2.1.1 The Initiators The modern start of cybernetics dates back from the first edition of the book of Norbert Wiener (1894–1964), *Cybernetics or Control and Communication in the Animal and the Machine* (Wiener, 1948). Norbert Wiener, Warren S. McCulloch, John von Neumann, and other colleagues, belonging to a group sponsored by the Macy Foundation and called "Teleological Society," recognized the importance of a new field of research (1943) that they decided, in 1947, to call *cybernetics* from the Greek *κυβερνήτικὴ*, which means the art of steering. The Teleological Society was also nicknamed "Cybernetical Club," an expression similar to "Cercle d'Etudes Cybernétiques" created in 1950 in Paris. The role of McCulloch (1898–1969) is not to be underestimated. His first contribution to the field was an article, with N. Pitts, devoted to the algebra of logics applied to nervous activity (McCulloch and Pitts, 1943). In opposition to Wiener, who considered Leibniz as the patron of cybernetics because of his attempt to build up a general calculus of logics, he put this new science under the aegis of Descartes, who proposed a kind of feedback in the framework of his theory of nervous transmission.

2.1.2 The Precursors In fact, the French word *cybernétique* had been introduced by Ampère (1843), in his classification of sciences. For him it represented the art of government, the same meaning Plato gave metaphorically to *κυβερνήτικὴ*, particularly in his dialogue on politics. The same year as Ampère, Trentowski introduced in Polish the word *kibernetiki*.

To this list we may add S. Odobleja who had an intuition of the universal role of feedback presented in a book (Odobleja, 1938, 1939) on what he called "psychologie consonantiste." Also from Romania, P. Postelnicu had a clear view of the general importance of feedback in a paper proposed in 1944 but accepted for publication only in 1968 (Postelnicu, 1968). Another precursor is Lafitte (1932), who had seen the philosophical importance of "machines réflexes."

2.2 Fundamental Concepts

2.2.1 Negative Feedback and Generalizations Control and communication are very important in Wiener's cybernetics. Depending upon both of them, regulation by *negative feedback*, already known for a long time, plays a prominent role. Watt's flyball governor gives a famous example of it, as does the clepsydra water supply. In all these kinds of regulation the problem is to maintain, as well as possible, an essential parameter of a dynamical system at a given value: the rotation speed in a steam engine for Watt's governor, the level of water in a reservoir for the clepsydra. In the case of Watt's governor, when the speed is too high, the steam supply is reduced through a well-known device based upon the action of centrifugal forces upon the flyballs. More generally the value of the parameter to be regulated is compared to its desired level. Based upon this comparison, a countermeasure is generated tending to decrease the parameter when it is too big and to increase it when too small. The fact that the actual value of the parameter (considered as the output) is compared to its desired value (considered as an input) justifies the word feedback. This feedback is said to be negative because of the action, generated by the value of the difference between the output and the input, tends to decrease this difference when it is positive and to increase it when it is negative.

Closer to us, the thermostat, which is used to maintain the temperature of a place close to a prescribed value, is another kind of regulator. More generally a device designed to make a temperature follow a given program as well as possible, despite perturbations, is a more refined type of regulator involving also a negative feedback. If $u(t)$ is the desired temperature at instant t, and $\theta(t)$ the temperature actually realized under the influence of a perturbation $v(t)$, $\theta(t) - u(t)$ is the gap whose absolute value is to be maintained as small as possible. Here $\theta(t)$ is the *output* of this system, $u(t)$ is an *input*, the one that is at the disposal of the user of the device, and $v(t)$ may be considered as another input but out of reach of the user. When the gap $\theta(t) - u(t)$, considered as a signal, is positive, it must generate some absorption of heat in order to make the gap decrease despite the perturbing influence of $v(t)$. This behavior may be represented, in the most simple case, by a differential equation such as

$$\begin{aligned}\dot{\theta}(t) &= \alpha[\theta(t) - u(t)] + \beta v(t)\\ &= \alpha\theta(t) - \alpha u(t) + \beta v(t), \qquad (38)\end{aligned}$$

where $\alpha < 0$ and β is sufficiently small.

In the above example the state $\theta(t)$ of the considered device is a mere scalar, but it could be a vector (represented by a column matrix). In the same way $u(t)$ and $v(t)$ also could be column matrices, α and β becoming respectively a square and a rectangular matrix. In this case, condition $\alpha < 0$ would be replaced by the strict negativity of the eigenvalues of matrix α, and the smallness of β by that of the elements of matrix β. These considerations open the way to more general cases, with or without feedback, represented, in the linear differential case, by the following multivariable equations:

$$X(t) = A(t)X(t) + B(t)U(t), \qquad (39)$$

$$Y(t) = C(t)X(t) + D(t)U(t), \qquad (40)$$

where input $U(t)$, state $X(t)$, and output $Y(t)$ are column matrices, $A(t)$ is a square matrix, and $B(t)$, $C(t)$, and $D(t)$ are generally rectangular matrices, all depending upon time. In such a differential system, input $U(t)$ is considered as a control upon state $X(t)$ and output $Y(t)$ as what is observed of $X(t)$. Then this differential system is said to be completely *controllable* if, for any initial and final instant t_0 and t_1 and for any state X_0 at t_0 and X_1 at t_1, there exists at least one control that brings the state X_0 to X_1. In fact there is an infinity of such controls, a situation that opens the way to the problem of *optimal control* with the works of Bellman (1957) and Pontryagin (1962). The system is said to be completely *observable* if, for any initial and final instant t_0 and t_1, the knowledge of input and output functions on the interval $[t_0,t_1]$ enables us to reconstruct the state function on this interval. Kálmán (1960) gave necessary and sufficient conditions for both controllability and observability. Of course, these results may be adapted to the linear recurrent case and to nonlinear equations, even with delay, whether deterministic or stochastic.

2.2.2 Signal and Information The second important concept upon which Wiener based cybernetics is that of communication or more precisely *signal* theory. His main results in this field are exposed in Wiener (1949), but founded upon more ancient results he obtained on Brownian motion and his generalized harmonic analysis. In this book, Wiener solves, in the framework of stationary time series, the problem of optimal elimination of an additive noise perturbing a signal and of optimal prediction of this signal. The solution, anticipating those initiated later, was achieved by Wiener by means of a frequency filter, but had been obtained earlier quite independently by Kolmogoroff (1941) in comparable but different terms.

Wiener considered the works of Claude E. Shannon on *information theory* as an essential part of cybernetics. Presented in Shannon's seminal article of 1948, they were published also in his book *The Mathematical Theory of Communication*, with an additional chapter by W. Weaver (Shannon and Weaver, 1949). Shannon considered, as did Wiener, a signal perturbed by an additive noise. But instead of trying to eliminate the noise as well as possible, his aim was to study the ability of a channel to transmit information, in both the discrete and continuous cases.

According to Shannon, a general communication system can be represented by a source of information producing an input message on which operates a transmitter giving an input signal suitable for transmission over a channel. The addition to this signal of a noise, coming from a source of noise, generates the output signal, which enters into a receiver, giving an output message that then reaches its destination (be it a conscious being or not) (see Fig. 10).

Let us consider the case of a discrete source of information giving, as an input

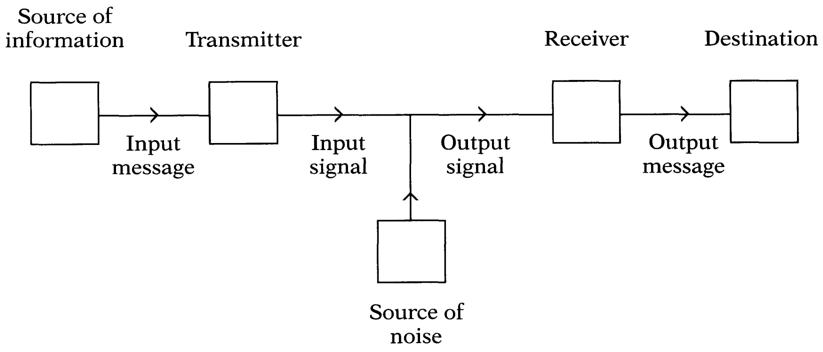

FIG. 10. Schematic view of a communication system.

message, a sequence of symbols chosen according to certain probabilities depending generally upon the symbol itself and the preceding choice. This input message is encoded into an input signal that is a sequence of other symbols chosen according to certain other probabilities. This input signal is perturbed by a discrete noise also of probabilistic nature. In such a case, the only one we shall present here, Shannon has shown that there exists a parameter C, the *channel capacity,* such that, if the *quantity of information* per unit of time produced by the source is less than or equal to C, there is a coding of the input message into the input signal such that the transmission over the channel, up to the output message, is realized with an arbitrarily small frequency of errors.

In the above statement, Shannon introduces what he calls quantity of information. The idea originated in statistics with the works of R. Fisher and continued with those of Nyquist (1924), also known for his diagram concerning feedback and stability, and Hartley (1928). The quantity of information of Shannon has no semantic meaning. It is only an index that increases with unexpectedness. So the quantity of information attributed to a message announcing that an event, with *a priori* probability p, has occurred is

$$I = -\log_2 p, \quad 0 \le p \le 1, \tag{41}$$

where $\log_2$ means logarithm with base 2. Of course $I > 0$, and when $p = \frac{1}{2}$, then $I = 1$. Consequently, the unit of quantity of information corresponds to the case where realization and nonrealization of the event are equiprobable. It initially had been given the name of Hartley and is currently called bit (binary digit).

Coming back to communication theory, we consider a discrete source of information generating a sequence of symbols chosen from a finite set $\{s_1, s_2, \ldots, s_n\}$ according to probabilities supposed here, for the sake of simplicity, independent of the preceding choices. So the probability of symbol s_i is p_i with $0 \le p_i \le 1$, $\Sigma_i p_i = 1$. Consequently, the quantity of information associated to the occurrence of symbol s_i is $-\log_2 p_i$ and the average quantity of information per symbol is, according to Eq. (41),

$$J = -\sum_i p_i \log_2 p_i, \tag{42}$$

with, by convention, $0 \log_2 0 = 0$. We easily see that $0 \le J \le \log_2 n$, the maximum being obtained when all the p_i are equal to $1/n$. If there are only two symbols, we have $p_1 = p$, $p_2 = 1 - p$, and the average quantity of information per symbol is

$$J = -[p \log_2 p + (1 - p) \log_2 (1 - p)]. \tag{43}$$

The maximum of 1 bit is obtained for $p = 1 - p = \frac{1}{2}$ (see Fig. 11). Coming back to the case of n symbols, the average quantity of information, per unit of time, produced by the source is J/τ if τ is the mean duration of the emission of a symbol. It is this quantity that is considered in the proposition of Shannon given above.

In statistical mechanics the *entropy* of a probability distribution $p_1, p_2, \ldots, p_n$ of the

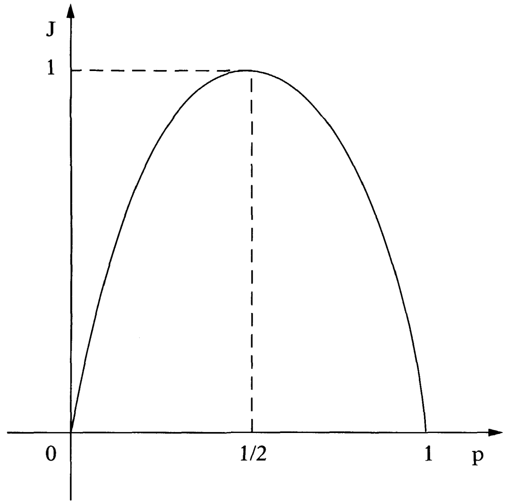

FIG. 11. Average quantity of information per symbol for an "alphabet" of two symbols of probabilities p and $1 - p$.

n possible states of a thermodynamical system is given by

$$S = -k \sum_i p_i \ln p_i,$$

where ln means the natural logarithm and k is Boltzmann's constant. The formal analogy between Eq. (42) and (43) was remarked by Shannon, who used the word "entropy" in place of average quantity of information per symbol. It also generated researches by Szílard (1929) and then by Mandelbrot (1953) (known also for his theory of fractals) and Brillouin (1956), which aroused the interest of L. de Broglie. They proposed explanations of the so-called Maxwell demon paradox, involved in a thought experiment supposed to show that the second law of thermodynamics (increase of entropy in a closed system) may be wrong at the microscopic level. These approaches are still controversial, and new theories have been proposed.

2.2.3 Isomorphism *Isomorphism* is another feature of cybernetics. In the very title of Wiener's book, the two words "animal" and "machine," to which we may add "society" if we consider an important chapter of this work, show that cybernetics aims, with at least the help of the concepts of feedback and quantity of information or more generally control and communication, at the recognition of structural analogies between, for example, the fields of the artificial, of biology, and of sociology. These structural analogies concern forms if we consider this word with its broadest meaning; they may imply, for example, a common kind of modelization. This is why isomorphism, the strongest case of analogy, that is to say a one-to-one correspondance between elements and relations between elements, from a field to another, is so important for cybernetics, even if in many cases isomorphisms are not perfectly realized.

2.3. Further Developments

2.3.1 Requisite Variety After the first modern approach to game theory by E. Borel, von Neumann greatly improved the initial results, mainly in his *Theory of Games and Economic Behavior,* in collaboration with Morgenstern (von Neumann and Morgenstern, 1944). Mandelbrot (1953) introduced the idea of a link between games theory and communication. He observed that in communication theory we have a transmitter who wants to communicate information with the help of a signal; the line; the receptor who expects to receive the information; and "nature," which passively spoils the signal with a noise. So we have a duel between transmitter and nature, a situation considered with great details in games theory.

The contribution to cybernetics of Ashby (1903–1972) involves his so-called principle of *requisite variety* proposed in Ashby (1956). This principle, when made more precise in a special case by Conant (1969), tells that the greater the capacity of a regulator to transmit information per unit time, through its feedback chain, the better its ability to resist successfully a perturbing noise. We see here concepts coming both from information and game theories. In its most general form, Ashby's principle says that in order to resist a great variety of possible aggressions it is necessary to dispose of at least the same variety of countermeasures—in short, that only variety can destroy variety.

2.3.2 Second-Order Cybernetics In *second-order cybernetics,* an expression due to Heinz von Förster, emphasis is put on observation not merely of a cybernetical device, or system, by an external observer but performed by the system upon itself and the outside world. It involves, in mathematical terms, the introduction of an *observation operator* (Vallée, 1951) and obviously auto-observation as well as *self-reference,* which was considered first by von Förster and developed later by Bråten (1982), Löfgren (1987), and Pask (1975), to whom we are also indebted for the concept of *conversation theory.* In the same context was introduced the concept of *perceptron,* a device able to reproduce, at least schematically, the perceptive properties of an observing system (Cellérier *et al.,* 1968). The iteration of the process of perception may give rise to a fixed point, that is to say an element of a set that is invariant under a given transformation of the set into itself. Here the fixed point represents, for the observing system, a stable way of acting, which von Förster called *eigen-behavior,* an expression already used by Jerne (1974), with a somehow different meaning, in the field of immunology. This approach enabled von Förster (1976) to propose an interesting interpretation, in terms of observation and *self-organization* (or *autopoiesis*), of Piaget's (1937) genetic epistemology, according to which the way an individual sees the world is built up progressively. Later eigenbehaviors were also considered by Varela (1980) in his researches on *autonomy* and self-organization, initiated by Maturana (1969), who introduced the idea of *operational closure.* We may note also the notion of *double bind,* or contradictory constraints, introduced in 1956 by Bateson (1972) in his theory of schizophrenia.

2.3.3 Cognition and Action We have seen that there are some links between cybernetics and game theory (*q.v.*). This is one of the reasons why cybernetics may be placed, at least partly, under the aegis of *action.* L. Couffignal even considered cybernetics as "the art of making action efficient." In an article entitled "Behavior, purpose and teleology," Wiener and some colleagues felt that the field that was to become cybernetics had something to do with action, that teleology, by definition, is involved each time a negative-feedback device tends to realize some predetermined purpose, or when a conscious being tries to achieve a given end (Rosenblueth *et al.,* 1943). The connotation with action is also to be found in the concept of controllability as well as optimal control.

The theory of *ago-antagonism,* presented by E. Bernard-Weil in his medical thesis of 1955 and much developed later, shows the role of simultaneous actions, of opposite natures, in the control of nonlinear systems, particularly in the field of medicine (Bernard-Weil, 1975). But action is not to be considered alone since it must be based upon *cognition.* This leads to *epistemo-praxiology,* where one considers a cybernetical system able to observe, decide, and act and so modify itself and the rest of the universe (Vallée, 1974, 1995). This approach involves new aspects of subjectivity due to *inverse transfer* of both epistemological and praxiological traits of the system considered. Obviously cognition and action lead to the science of the artificial as foreseen by Simon (1969).

2.3.4 Links with Systems Theory and Synergetics Ludwig von Bertalanffy (1901–1972) introduced the concept of *general systems* (or *system*) *theory,* a translation of the German words "allgemeine Systemlehre" (von Bertalanffy, 1945), often improperly seen as a theory of "general systems" instead of a general theory of systems (von Bertalanffy, 1968). For von Bertalanffy, a system is a set of elements in interaction. So we may consider cybernetics, involving elements interacting through feedbacks and flows of information, as a part of general system theory. In brief we can say *systems theory* or *systemics,* remembering, from a historical point of view, that A. Bogdanoff had partly forseen it, in 1912, with his tectology or universal science of organizations.

Among the main concepts, or ideas, of systems theory that have links with cybernetics or with cybernetics of the second order, we can quote homeostasis, local and global points of view, open systems, order and noise, ... The concept of *homeostasis* was used by C. Bernard, in his introduction to experimental medicine (1865), to express the stability of physiological parameters such as blood pressure or temperature, but the word was chosen by Cannon (1930) and used by von Bertalanffy. It is typically cybernetical and implies negative feedbacks. It led Vendryès (1942) to a theory of general autonomy. Up to a certain point, the opposition between *local* and *global* points of view exists already in cybernetics if we consider the existence of long informational transmission chains. Systems theory is more radical and often insisted upon the importance of a global view, opposed to the mere local one leading to the so-called reductionist approach that proposes decomposition of physical systems into parts as the best way to study them. This attitude has been often attributed to Descartes who, in fact, had in mind only the decomposition of logical difficulties into parts. Local and global points of view have not to be taken too literally; both are necessary, as Pascal pointed out. For von Bertalanffy in an *open system* there is a flow of matter and energy (and even information) through its boundary. A cell and a living being are examples of open systems as well as *dissipative structures* considered by Prigogine (1969). This concept helps cybernetics to extend its domain of application. The idea that it is possible to get *order from noise* was proposed by von Förster (1960). This is not to be understood in a naive way. It must mean that noise can play a triggering role in the emergence of a potential ordered structure, so giving rise to self-organization, a concept of second-order cybernetics. This happens with a physical system, subject to a possible *bifurcation* in the evolution of its state, when, because of some fluctuation generated by noise, a certain parameter reaches a critical value.

With this type of emergence we can see some links of cybernetics with *synergetics*, an interdisciplinary field created, in 1969, by Hermann Haken (see Sec. 1), dealing with a cooperation of parts of a system able to generate self-organization. In particular, synergetics deals with open systems and order parameters that act both as control and information agents.

2.4 A Tentative Chronology of Cybernetics

Obviously the concepts upon which cybernetics is based have interfered in a very complex way, generating new concepts and interacting with other fields more or less close to it, as we have seen in the previous sections. Neglecting details and too remote historical influences, we present now a tentative diagram (Fig. 12) showing the main interactions between concepts and fields taking chronology into account.

FIG. 12. Chronology of cybernetics.

fields, from philosophy to pedagogy. Here we shall only mention briefly some of them.

The whole domains of automatics, control engineering, and even *fuzzy control,* based upon the theory of fuzzy sets where elements have a degree of belonging to a set (Zadeh, 1965; see THEORY AND APPLICATIONS OF FUZZY LOGIC), are greatly indebted to cybernetics just as cybernetics has been indebted to the theory of regulators at its beginning. More precisely, *robotics,* with the role played by artificial organs of perception and effectuation, may be seen as inspired by cybernetics. We can include here *computer science* (or *informatics*) and also *artificial intelligence,* pattern recognition, and more recently *artificial life,* which aims at the realization of artifacts reproducing traits of natural life. The whole field of communications, with the part played by information theory and signal processing, and the importance taken by the possibilities opened, under the name of cyberspace, by worldwide networks, is essentially cybernetical.

Biological modeling, and biomedical systems, with homeostasis and self-organization, are domains of application of cybernetics as Wiener had foreseen it, as well as neurology and brain studies.

Economics and *management,* with the works of Lange (1962) and Beer (1972), have also found interesting bases in cybernetics, as well as the fields of *ecology* and *sociology* where modeling plays a part.

In what directions can we expect cybernetics to be developed? Obviously artificial intelligence, artificial life, robotics, and all the world of the artificial offers a very favorable field, as well as those of biology, sociology, economics, and management. This is not surprising if we look at the table of contents of Wiener's book on cybernetics, which is partly a program of research not yet completed. But there are other possibilities in the domains of control and communication. Feedback has been mainly studied in the linear case, be it unidimensional or multidimensional. Indeed, the nonlinear case has not been forgotten, but it is far from being completely known if indeed it ever can be: New examples of unstability of cybernetical systems have arisen involving "chaotic" behaviors. Classical information theory suffers from the important limitation, pointed out by Shannon, that it does not take into account the semantical aspects. Despite interesting approaches, semantics of information still needs to be developed. The links between quantity of information, entropy, and even complexity are still arousing a great interest and offer challenging problems.

GLOSSARY

Associative Memory: Memory that complements an incomplete set of data to a complete set on account of stored data or rules.

Attractor: A set of points in state space toward which the state vector is attracted.

Basin of Attraction: Set of points in state space from where the state vector can be attracted toward the attractor.

Center Manifold: Set of variables with neutral stability.

Center Manifold Theorem: A mathematical theorem that allows one to express the variables of the stable manifold by means of those of the center manifold.

Chaos: In this article chaos is meant as deterministic chaos.

Critical Fluctuations: Close to a phase transition or nonequilibrium phase transition the state vector undergoes particularly large fluctuations.

Critical Slowing Down: Close to a phase transition or nonequilibrium phase transition the state vector relaxes very slowly.

Fixed Point, Stable: Point attractor.

Information: This word is used in the sense of Shannon and measures the number of bits.

Limit Cycle, Stable: Attractor connected with a periodic motion.

Lyapunov Exponent: Exponent characterizing the convergence or divergence of initially nearby trajectories.

Quasiperiodic Motion: The time dependence of the state vector can be described as a superposition of exponential functions with exponents containing linear combinations of several frequencies with integer coefficients.

Stability: A system is stable when after a perturbation it relaxes toward its former state.

Symmetry Breaking: Close to a phase transition or nonequilibrium phase transition the order parameter(s) make a choice between different equally possible states.

Synergetics: Word constructed from Greek meaning science of cooperation.

Trajectory: Curve in state space along which the state vector moves according to the evolution equation.

INTRODUCTION

From the earliest days of polymer science, the novel and diverse behavior of newly synthesized materials was immediately recognized—for example, after the discovery of the polymerization of nylon, researchers realized that a wide variety of properties was available from a single polymer by careful manipulation of processing conditions. Thus, nylon fibers could be spun into a family of fibers with properties conveniently controlled by extent of draw, draw temperature, post heat-setting treatment, etc.

The wide range in polymeric behavior stems from the enormous spectrum of structural states that polymers can assume: solutions, melts, glasses, crystals, liquid crystals, gels, and rubbers. This in turn stems from the chemical diversity of the macromolecules. Moreover, because of the tremendous conformational diversity of a polymer, a given polymer can yield an immense variety of structures! It is hard to imagine a material replacing rubber's unique physical properties, which essentially derive from conformational diversity.

In addition to technically relevant properties such as reversible deformation of several hundred percent (rubber elasticity) and Young's moduli 1.5 times that of steel (rigid rod fibers), polymer molecules offer a scientist a fertile area for basic study. From flexible chains to rigid rods, scientists have been seeking to understand polymeric behavior. This task is challenging, because polymeric materials are highly complex. They are complex because polymer synthesis often does

digital Encyclopedia of Applied Physics

not result in simple, single-component species, they are complex because frequently their organization in the solid state takes place on several length scales, and they are complex because the relatively long time scales required to reach equilibrium are frequently much longer than experimentally feasible. While a good deal of the complexity of polymers is unavoidable, the difficulties arising from their synthetic complexities have been reasonably addressed via the production of model materials by the modern synthetic polymer chemist.

By *model material,* we mean a species for which the parameters of molecular characterization are very well represented by the ensemble average. That is, every molecule is essentially identical to every other (monodisperse ideal population), or the collection of molecules corresponds to a valid statistical assembly of species arising from a given stochastic process (ideal random population). Experiments conducted on model materials benefit from the specificity of response to the molecular variables and allow much more precise interpretation and testing of structure–property relationships.

Over the past fifty years, polymer chemists have made important advances in the control of macromolecular chain structure. Initially, most polymers were produced by polymerizations in which the chemical linking events were more or less randomly selected from a large number of possibilities, hence making the product macromolecules highly complex species. The chemist's prime goals were high yields and high molecular weight. This fact of dispersity in composition, in stereochemistry, in sequence distribution, and in molecular length meant that the resultant material could only be characterized for *average* molecular properties. And, as became evident, different physical probes were sensitive to different averages or different aspects of the molecular distribution. For example, polydispersity causes the progression of molecular-weight averages $\bar{M}_z > \bar{M}_w > \bar{M}_n$, where $\bar{M}_z$ is the z-average molecular weight (see Sec. 2.1) (measured via sedimentation equilibrium), $\bar{M}_w$ is the weight-average molecular weight (via light scattering), and $\bar{M}_n$ is the number-average molecular weight (via osmometry). Molecular weight and polydispersity will be discussed more in Sec. 2.1.

Given that polymer materials contained fairly broad molecular-weight distributions, early workers by necessity satisfied themselves with more qualitative measurements than were possible with pure materials composed of a collection of identical macromolecules. Quantitative materials science (akin to that currently practiced in, say, the field of semiconductors) is just beginning to take place for polymers with the careful, precise characterization of highly specific behavior replacing the former measurements, which were almost always significantly broadened by the spread in the molecular response stemming from the collection of diverse species in a given "pure" sample. The availability of these model materials has facilitated studies of, for example, polymer dynamics, adsorption, block-copolymer morphology, crystalline-polymer morphology, blend miscibility, diffusion (both tracer and self-diffusion), rheology, and unperturbed chain dimensions.

As we approach the twenty-first century, three activities are especially important in the changeover from such statistically complex materials of the past to the new, precisely defined, materials of the future. First, activity in novel synthetic methods, including recombinant DNA technology, promises synthesis of uniquely specific macromolecules. Second, advances in instrumentation to measure molecular properties of these substances accurately are continually being made. Third, the significant growth of computational power to model and of theoretical power to predict, ever more realistically, such molecules provides good prospects for future understanding. All three of these endeavors, plus the merger of ideas and techniques of the polymer scientist with those of the molecular biologist and the closer coupling of the polymer chemist with the materials scientist and physicist, will contribute in major ways to the success of the "physics of macromolecules."

1. SYNTHESIS OF MODEL POLYMERS

1.1 Living Anionic Polymerizations

Chain polymerizations occur by the successive addition of monomers to a free-radical, cationic, or anionic reactive center.

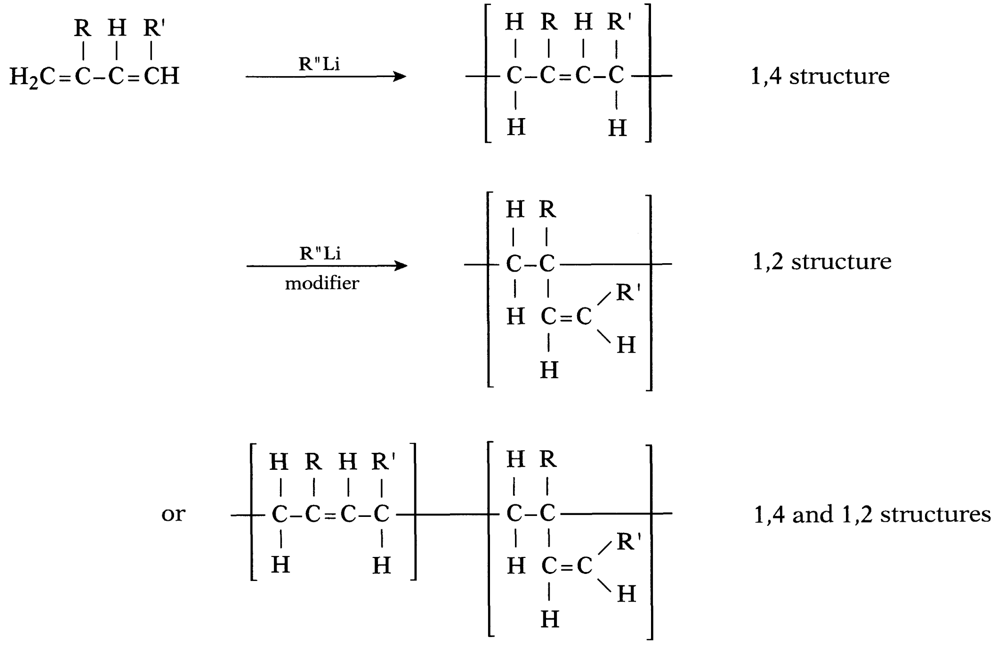
These methods are commonly applied to the polymerization of vinyl monomers CH_2═CHR, where R represents a simple or complex substituent group. Living polymerizations refer to chain polymerizations that do not exhibit spontaneous termination and consequently maintain their reactive centers indefinitely. While there are pseudoliving polymers having free-radical or cationic reactive centers, strictly living polymers are limited to anionic systems under special reaction conditions. The characteristics of living anionic polymerization have been exploited to create nearly monodisperse homopolymers, linear polymers along which the monomer type changes, end-functionalized polymers, and a host of nonlinear polymer architectures (see Fig. 1).

1.1.1 Linear Polymers Living anionic polymerization systems are obtainable with organolithium initiators and hydrocarbon solvents under conditions that exclude oxygen and proton-donating impurities, such as water. These conditions provide rapid initiation of the propagating chains and a stable anionic reactive center with no effective termination mechanism. Because the propagating chains begin polymerizing nearly simultaneously and grow until all the monomer is consumed, the polymer chains have nearly monodisperse molecular-weight distributions. (Molecular-weight averages and determination are discussed more fully in Sec. 2.1.) The molecular weights of these materials are controlled by the simple expedient of manipulating the ratio of monomer $[M]$ to initiator $[I]$ because each molecule of the latter will generate a growing chain. Thus, from the standpoint of the number-average degree of polymerization, DP_n, we have

$$DP_n = [M]_0/[I]_0, \qquad (1)$$

where the subscript 0 denotes the initial reactant concentrations. These two characteristics, nearly monodisperse homopolymers and controllable molecular weight, are paramount to polymer physicists studying molecular-weight–dependent properties such as viscosity, diffusion, and chain conformation.

Another characteristic of the organolithium-based polymerization systems in hydrocarbon solvents is the possible control of the microstructure of polymers prepared from diene monomers (CH_2═CR—CH═CR'H). The relative amounts of 1,2 and 1,4 addition in a polydiene are altered by modifiers such as ethers (ROR′), amines (NR_3), and diamines (R_2N—CH_2CH_2—NR_2):



(2)

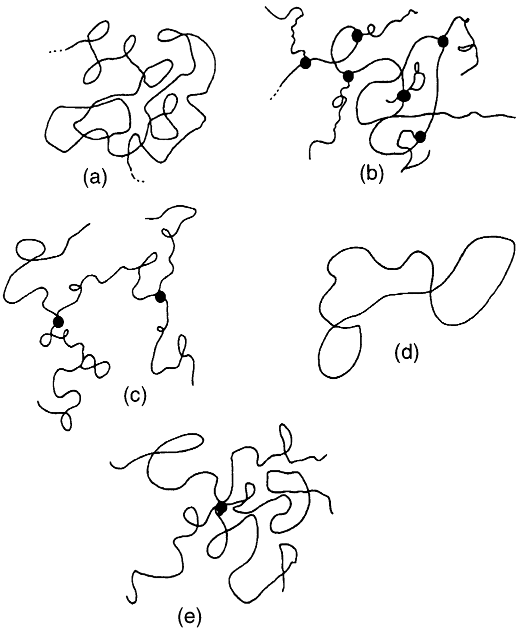


FIG. 1. Schematic of macromolecules with various architectures: (a) linear, flexible chain; (b) graft; (c) H-shaped; (d) ring; (e) star (after Fetters and Thomas, 1993).

The polymers containing both 1,2 and 1,4 addition possess a specific type and level of branching that is not readily accessible by other synthetic routes. The carbon–carbon double bonds of the polydienes can be saturated to produce polyolefins that retain the narrow molecular-weight distribution and the branching of the parent material. Though typically accomplished by catalytic hydrogenation, the saturation reaction can also be performed with deuterium or a mixture of deuterium and hydrogen in order to label the polymers for neutron scattering, forward recoil spectrometry, secondary-ion mass spectrometry, or other experiments using isotopic contrast.

The retention of chain-end reactivity has allowed the preparation of block copolymers through the sequential polymerization of different monomers. The sequential addition of monomers to a reactive center is used routinely in industry to produce diblock and triblock copolymers (two monomer types) and triblock terpolymers (three monomer types). In theory there is no limit to the number of sequential additions of monomer and thereby only practical limits to the number of blocks in a copolymer. Two or more different monomers are used to build up a block copolymer, though there are constraints as to the type of monomers that can be added. For example, methyl methacrylate monomers can be added to a polystyrene propagating reactive center, but styrene monomers cannot be added to poly(methyl methacrylate) propagating chain ends.

The conditions under which these polymerizations are conducted require attention. Generally, an acceptable temperature range is 0 to 50 °C. Higher temperatures will lead to active-center deactivation via, for example, lithium hydride elimination or metallation events (Kern *et al.*, 1972; Broske *et al.*, 1987; Pennisi and Fetters, 1988). If an active center on a propagating polymer chain is displaced to another substance, the reaction is termed chain transfer and results in a decrease in the molecular size of the polymer product. In particular, solvents that can cause chain transfer are to be avoided. Toluene is often cited as the polymerization solvent. This is an unsuitable choice, since the following occurs (Gatzke, 1969):

$$\mathrm{P^-Li^+ + CH_3}\text{—⬡} \rightarrow \mathrm{PH + LiCH_2}\text{—⬡}, \qquad (3)$$

where P^- and P represent the polymer chain with and without a propagating anionic center, respectively. Such reactions clearly will distort the molecular-weight distribution.

Care must also be exercised in the termination of these active centers, since trace amounts of oxygen in, for example, methanol will lead to chain coupling (Fetters and Firer, 1977). Ideally, deactivation of the active centers occurs as follows:

$$\mathrm{P^-Li^+ + CH_3OH \rightarrow PH + CH_3OLi}. \qquad (4)$$

The presence of oxygen can cause the side reaction

$$\mathrm{(P^-Li^+)_2 + \tfrac{1}{2}\,O_2 \rightarrow PP + Li_2O}. \qquad (5)$$

The transition state of the chain ends involves free radicals, which readily couple to yield "doublet" material, with a subsequent distortion of the molecular-weight distribution. This dimerization event is also promoted by the fact that the polymers themselves are associated as dimers in hydrocarbon solvents as a consequence of electron-deficient bonding present in organolithiums.

1.1.2 Functionalized Polymers In recent years there has been a growing interest in the preparation of well-defined polymers with terminal functional groups. The primary motivation for this interest in functional groups is their potential for the following applications:

1. cross-linking reactions in which polymers are bonded to two or more other polymers to form a network of polymers;
2. chain extension or branching;
3. reactions with functional groups on other polymer chains;
4. polymer modification to produce surfactant-like properties—that is, two distinct chemical affinities on a polymer;
5. initiation of polymerization of other monomers; and
6. reversible ionic association.

Some of the feasible structures are schematically given in Fig. 2 where X and Y indicate the locations of functional groups. The most well-defined and exploited route to these materials to date has been lithium-based living anionic polymerizations. Some examples of the functional groups are given in Table 1. The foregoing also serves to summarize some of the nonfunctionalized structures that have been prepared via anionic polymerizations.

One of the most useful and widely used functionalization reactions has been the carboxylation of polymeric anions using carbon dioxide. Although intrinsically a simple reaction, it yields a complex mixture of products involving carboxylated polymer, the dimeric ketone, and trimeric alcohol, as noted previously.

Initially, it was found that the coupling and linking side reactions could be virtually eliminated in systems where the polystyrillithium was complexed with a base such as tetrahydrofuran or tetramethylethylenediamine (Quirk *et al.*, 1989). An alternative route involved the solid-state (achieved by freeze-drying the polystyryllithium) exposure of the active centers to CO_2 at atmospheric pressure. In both cases the yield of carboxylated polystyrene was >99% (Quirk and Yin, 1992; Quirk *et al.*, 1992).

The use of $^{13}CO_2$ revealed that approximately 15% of the —COOH groups were present on the aromatic ring. In other words, although carboxylation efficiency was 99% or greater, nonetheless two types of carboxylic acid groups were present. Ring carboxylation was nearly eliminated for the reaction scheme that involved addition of CO_2 to the modifier-complexed polystyryllithium, in benzene solution.

The foregoing serves to highlight the necessity of a thorough and exhaustive characterization of functionalized polymers in order to establish confidence in the efficacy of the chemistry used. The review of Quirk (1992) is recommended as a thorough brief-

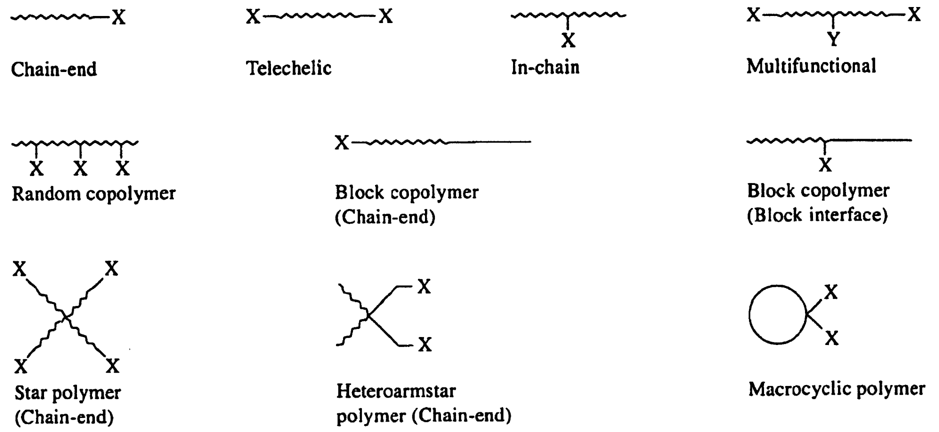

FIG. 2. Schematic of functionalized model polymers with various architectures (after Quirk, 1992). X and Y represent functional groups. Straight and zigzag lines represent different linear polymer chains.

ing on this topic. For more about characterization of functionalized polymers see Sec. 2.2.

1.1.3 Polymers with Complex Architectures Living anionic polymerization methods can be used to produce well-defined polymers of complex architecture. The retention of chain-end reactivity allows living polymers (homopolymers or block polymers) to be joined to an existing chain to form a grafted structure [Fig. 1(b)] with well-defined branch length and branch composition. Alternatively, homopolymers or block polymers with reactive chain ends can be bound to one another forming H-shaped or star structures [Figs. 1(c) and 1(e)]. There is a variety of chemical reactions that can be used to build these complex architectures.

The preparation of model star polymers is best approached via the application of chlorosilanes as the linking agents and the lithium counterion in place on the terminal active center. This approach was first used by Morton *et al.* (1962) for the preparation of three- and four-armed polystyrene stars. For example, the reaction for a four-armed star is

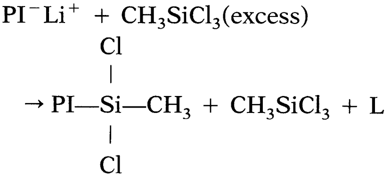
$$4P^-Li^+ + SiCl_4 \rightarrow P_4Si + 4LiCl, \qquad (6)$$

where P denotes a linear polymer. Using chlorosilane linking agents, controlled functionalities as high as 128 have been obtained, which are multiply branched "dendrimer"-type molecules (Roovers *et al.*, 1993).

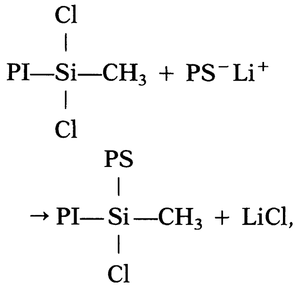
The chemistry in question has allowed the sequential buildup of star structures including

1. asymmetric homopolymeric materials in which the arms of the star are of the same monomer type but of different lengths (Pennisi and Fetters, 1988);
2. single-graft, multicomponent A_2B polymers having a linear backbone of component A and a single-grafted branch of component B (Mays, 1990); and
3. mixed-armed stars, or mikta-armed stars, ABC, in which each of the arms in a three-armed star contains a different monomer type (Hadjichristidis *et al.*, 1993), where A is polyisoprene (PI), B is polystyrene (PS), and C is polybutadiene (PB).

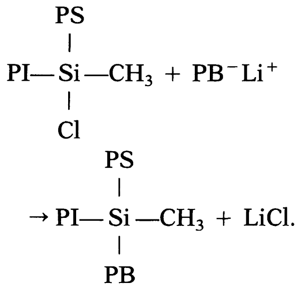
The mikta-armed stars rely on the reaction sequences



$$PI^-Li^+ + CH_3SiCl_3(\text{excess}) \rightarrow PI\text{—}\overset{\overset{Cl}{\vert}}{\underset{\underset{Cl}{\vert}}{Si}}\text{—}CH_3 + CH_3SiCl_3 + LiCl, \qquad (7a)$$



$$\mathrm{PI}-\underset{\mathrm{Cl}}{\overset{\mathrm{Cl}}{\mathrm{Si}}}-\mathrm{CH_3} + \mathrm{PS^-Li^+} \rightarrow \mathrm{PI}-\underset{\mathrm{Cl}}{\overset{\mathrm{PS}}{\mathrm{Si}}}-\mathrm{CH_3} + \mathrm{LiCl}, \tag{7b}$$



$$\mathrm{PI}-\underset{\mathrm{Cl}}{\overset{\mathrm{PS}}{\mathrm{Si}}}-\mathrm{CH_3} + \mathrm{PB^-Li^+} \rightarrow \mathrm{PI}-\underset{\mathrm{PB}}{\overset{\mathrm{PS}}{\mathrm{Si}}}-\mathrm{CH_3} + \mathrm{LiCl}. \tag{7c}$$

This approach permits the individual arms to be independently characterized along with the resultant mikta-armed star. The combination of size-exclusion chromatography (SEC), nuclear magnetic resonance (NMR) spectroscopy, refractive-index measurements, and light scattering provided the pedigree that unequivocally demonstrated that the desired ABC structure was obtained. The work of Iatraou and Hadjichristidis (1992) is a demonstration of how a model material can be prepared *and* properly characterized.

1.2 Stereospecific and Sequence-Specific Polymerizations

Monomers having a chiral center can be connected head to tail to produce atactic, isotactic, or syndiotactic polymers; see Fig. 3. While living anionic polymerizations are uniquely capable of producing nearly monodisperse molecular-weight polymers, well-defined block polymers, and specified architectures, the anionic synthetic route is not capable of producing stereospecific polymers. Nonetheless, the atactic polymers synthesized by anionic polymerizations are indeed model polymers, because the mean tacticity of the ensemble, i.e. random, sufficiently defines the tacticity of individual molecules.

Stereospecificity occurs when the polymerization reaction includes a coordination mechanism, as is possible with Ziegler–Natta initiators. Since the original discoveries of Ziegler and Natta in the 1950s, an ever-increasing number of initiators of the Ziegler–Natta type has emerged (Boor, 1979). Ziegler–Natta initiators encompass literally thousands of different combinations of a group I–III organometallic compound and a compound of a group IV–VIII transition metal. Subtle changes in these initiators can significantly alter the stereospecificity and the reaction rate, allowing polymerizations to be tailored for specific monomers. Regrettably, much of this tailoring is accomplished empirically on account of the limited knowledge of the mechanisms.

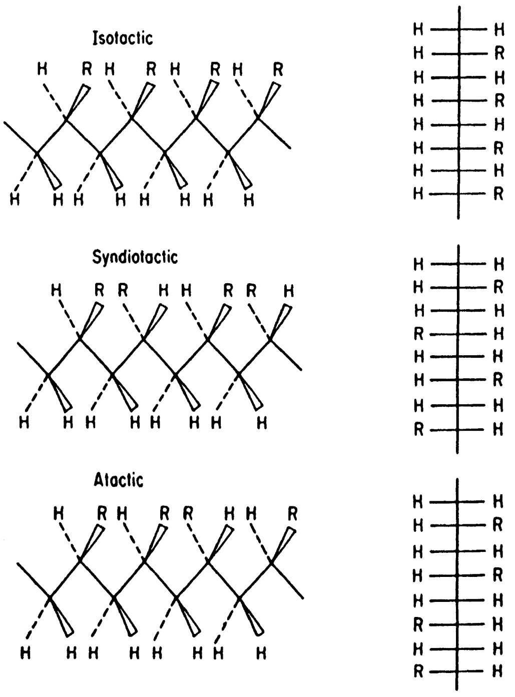


FIG. 3. Different polymer configurations of monosubstituted polyethylene $(CH_2—CHR)_n$. The dotted and triangular lines represent bonds to substituents below and above the plane of the carbon–carbon chain, respectively. (After Odian, 1981.)

As a specific example of stereoregular polymerization, Ishihara *et al.* (1988) have recently succeeded in preparing and characterizing highly syndiotactic polystyrene and substituted polystyrenes. A variety of mixtures containing methylaluminoxane and a titanium compound [$TiCl_4$, $Ti(OEt)_4$, or (η-C_5H_5)$TiCl_3$] yielded syndiotactic product at room temperature. As in the case of living anionic polymerization, measures must be taken to eliminate oxygen and moisture from the materials and the reaction vessel. The ^{1}H NMR spectra are used to delineate clearly between atactic, isotactic, and the new syndiotactic polystyrene. This new material is an important semicrystalline thermoplastic polymer with a high melting temperature (~270 °C), high crystallinity, and excellent chemical resistance.

In addition to stereoregular polymers, metal-catalyzed polymerizations can produce perfectly alternating copolymers of monomers A and B, i.e., . . .ABABABAB. . . (Hirai *et al.*, 1979; Galvin, 1991). For example, Galvin added methyl methacrylate to a toluene solution of an aluminum catalyst ($Et_3Al_2Cl_3$). The subsequent addition of styrene yields a strictly alternating copolymer as determined by ^{1}H and ^{13}C NMR. These materials have been used to investigate the importance of sequence distribution on blend miscibility by comparing to a randomly sequenced copolymer produced by free-radical polymerization (Galvin, 1991; Winey and Galvin, 1993; Winey *et al.*, 1996). Figure 4 shows transmission electron micrographs of two ternary blends containing equal amounts of poly(styrene-*co*-methyl methacrylate) copolymer, homopolystyrene, and homopoly(methyl methacrylate). The blends containing the random and alternating copolymers exhibit three and two phases, respectively, indicating that this small-scale difference in monomer sequence is sufficient to alter bulk miscibility. The study of sequence-specific copolymers awaits synthetic routes that can produce a full range of sequences (random, alternating, multiblock, block) for a selection of monomers having different interaction characteristics.

Note that, to date, these stereoregular and sequence-regular polymers can only be produced with broad molecular-weight ranges. Therefore, fractionation to reduce the polydispersity is required prior to studying molecular-weight–dependent properties.

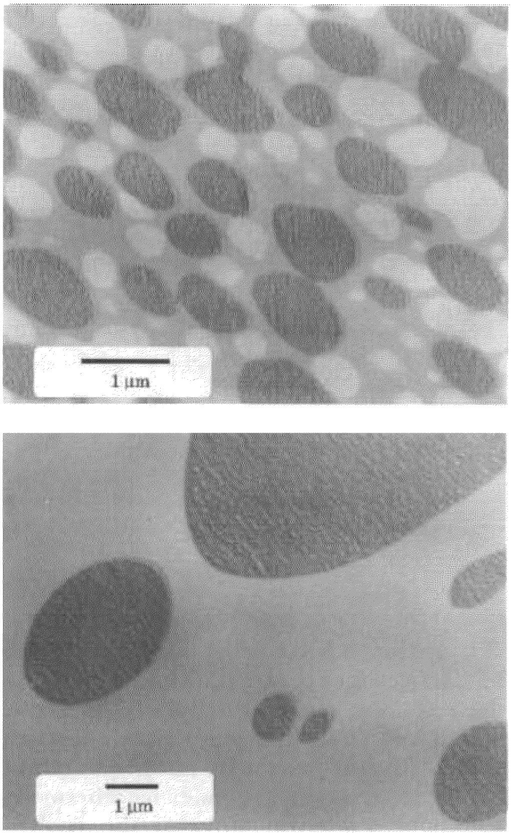

FIG. 4. Transmission electron micrographs of ternary blends containing 33% poly(styrene-*co*-methyl methacrylate), 34% poly(methyl methacrylate), and 33% polystyrene. (top) Copolymer has a random monomer sequence; (bottom) copolymer has a strictly alternating monomer sequence. Striations in the darkest phase are due to knife chatter while microtoming.

1.3 Recombinant DNA Methods

The last class of model polymer synthesis to consider is one in which every aspect of the resultant polymer is model. Recombinant DNA methods produce essentially absolute uniformity of molecular weight, stereochemistry, and sequencing. The biological sciences originally developed these techniques to study the biological function of genes and proteins and to duplicate the properties of naturally occurring structural proteins such as silks and collagens. Recombinant DNA methods are now being used to synthesize new materials designed either to mimic biological activity or to investigate polymer physics.

The recombinant DNA procedure begins with the selection of a specific sequence of amino acids, and then a complementary DNA strand is synthesized producing a synthetic gene. Through a sequence of steps, this synthetic gene replaces a naturally occurring gene sequence in bacterial cells such as *E. coli.* As the cells grow, an amino acid polymer is expressed and subsequently purified. The success of this method requires limited loss of the synthetic gene material from the bacteria, efficient transcription from the synthetic DNA to RNA, efficient translation from the RNA to the new protein, and good stability with limited toxicity of the new protein in the bacteria. Current strategies exist to combat these challenges, and multigram quantities can be successfully prepared by cloning and expressing artificial genes (Tirrell *et al.,* 1991).

Recombinant DNA methods are beginning to be used to construct chemically simple peptides that are capable of mimicking specific biological functions. Such studies attempt to distill the essential aspects of the structure from the highly complex natural peptides and to engineer these aspects into synthetic peptides. Synthetic proteins are being studied as novel electron-transfer and catalytic systems. For example, DeGrado and Dutton have designed and prepared water-soluble, four-helix bundle peptides containing 62 amino-acid residues in an effort to reproduce the extremely high electron-transfer efficiency of photosynthesis (Robertson *et al.,* 1994; Choma *et al.,* 1994). These peptides have specific metal-binding sites, which

1. bind a large rigid macrocycle (heme) to form redox sites and
2. provide tertiary structure, which is common in natural proteins.

The synthetic heme-binding protein can self-assemble and mimic the spectral and electrochemical properties of natural heme-binding proteins. This and other work have established the feasibility of designing functional synthetic proteins. However, a more complete understanding of the complex interdependence of the peptide structure and properties is required to guide the design and selection of peptides prior to synthesis by recombinant DNA methods.

Recombinant DNA methods can also produce new proteinlike polymers for the study of and uses as polymeric materials. In general, these polypeptides are longer and more periodic in their sequencing than natural polypeptides, which has required modification of the biological synthesis methods to accommodate their propensity to crystallize. Of current interest is the extension of the recombinant DNA methods to include non-natural amino acids. Tirrell and coworkers have used selenomethionine in place of methionine in the sequence, $[(\mathrm{Gly}\cdot\mathrm{Ala})_3\cdot\mathrm{Gly}\cdot\mathrm{SeMet}]_9$, which was designed to form lamellar crystals with selenium atoms on the fold surfaces (Krejchi *et al.,* 1994). The extensive incorporation of fluorine has also been accomplished by using *p*-fluorophenylalanine (pfF) in the sequence $[(\mathrm{Ala}\cdot\mathrm{Gly})_3\cdot\mathrm{pfF}\cdot\mathrm{Gly}]_{13}$ (Yoshikawa *et al.,* 1994). These fluoropeptides may exhibit properties related to conventional fluoropolymers such as low surface energy, low coefficient of friction, and excellent solvent resistance.

2. CHARACTERIZATION OF MODEL POLYMERS

Thorough characterization of a polymer is necessary for it to be classified as a model material. The details of polymer characterization are dictated in part by the synthesis method used; thus this section addresses primarily the living anionic synthetic route.

2.1 Molecular Weight and Polydispersity

Molecular-weight characterization of polymers is complicated by the fact that every polymerization route produces species that differ in molecular weight, with the notable exception of the recombinant DNA techniques. Model polymerizations strive to produce materials in which the various molecular-weight moments are, within experimental error, virtually identical.

The advent of size-exclusion chromatography (SEC) (also called gel permeation chromatography, GPC) allows detailed and rapid insight into molecular-weight distributions. SEC is based on the principle that the path a molecule takes through a porous medium depends on its molecular size. In the SEC experiment a polymer solution is injected into a series of columns that are packed with porous beads. A carrier solvent is precisely pumped through the columns, and a detection system at the end of the columns, typically intrinsic viscosity and/or index of refraction, determines the amount of polymer in the elution volume relative to the pure solvent as a function of time. The elution time, that is, the time between the injection of the solution and the elution of polymer, is shortest for the highest molecular-weight fraction of a polymer sample, because larger molecules flow past rather than reside in many of the cavities. Molecular weights are determined from the elution times by calibrating the apparatus with a set of molecular-weight standards.

A nearly monodisperse homopolymer polymerized using organolithium initiators produces a monomodal, narrow peak shape using SEC. Six 30-cm SEC columns are recommended to obtain suitable resolution; the columns may have mixed or single porosity without substantially altering the results. Fewer than six columns will mask complexities in the molecular-weight distributions that arise from less than ideal polymerization or coordination reactions. Figure 5 compares chromatographs obtained using two, four, and six columns, in which the bimodal nature of the particular molecular-weight distribution is most evident with six columns. The SEC data are used to calculate the molecular-weight moments or molecular-weight averages defined as follows: number-average molecular weight,

$$\bar{M}_n = \sum N_i M_i \Big/ \sum N_i; \tag{8}$$

weight-average molecular weight,

$$\bar{M}_w = \sum w_i M_i = \frac{\sum N_i M_i^2}{\sum N_i M_i}; \tag{9}$$

z-average molecular weight,

$$\bar{M}_z = \frac{\sum w_i M_i^2}{\sum w_i M_i} = \frac{\sum N_i M_i^3}{\sum N_i M_i^2}; \tag{10}$$

(z + 1)-average molecular weight,

$$\bar{M}_{z+1} = \frac{\sum w_i M_i^3}{\sum w_i M_i^2} = \frac{\sum N_i M_i^4}{\sum N_i M_i^3}, \tag{11}$$

where $w_i = c_i/c$ denotes the weight fraction of species i in the polymer and N_i is the number of moles of species i with the molecular weight M_i. Note that the other common methods for determining molecular weight determine only one of these moments.

Table 2 shows the ratios of these various moments for anionically polymerized 1,4-polybutadienes with molecular weights as low as 10^3. As indicated by ratios near unity, these SEC results indicate that the polybutadienes have nearly monodisperse molecular-weight distributions. As expected, the heterogeneity indices decrease as molecular weight increases. These three ratios or heterogeneity indices serve as the *complete and necessary* pedigree insofar as the length heterogeneity characteristics of a polymer are concerned.

A cautionary note is in order regarding the oft-cited, and often misleading, ratio of $\bar{M}_w/\bar{M}_n$, the so-called polydispersity index, as

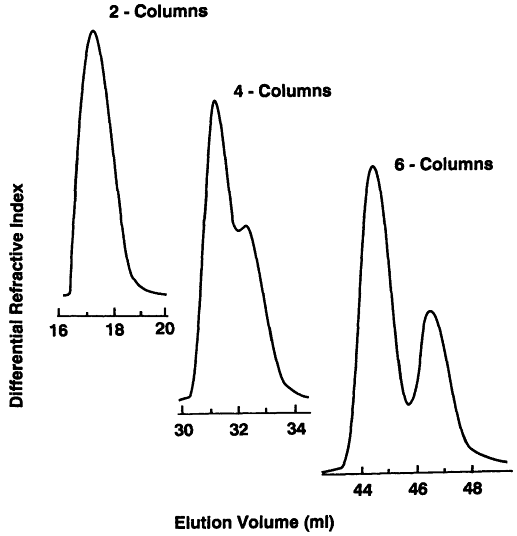

FIG. 5. SEC chromatographs showing improved resolution with increasing number of columns.

Table 2. SEC heterogeneity evaluations for low-molecular-weight polybutadienes.[a]

$\bar{M}_w \times 10^{-3}$ (g/mol)	$\bar{M}_w/\bar{M}_n$	$\bar{M}_z/\bar{M}_w$	$\bar{M}_{z+1}/\bar{M}_z$

[a] Polymerization of polybutadiene in cyclohexane at 20 °C with *tert*-butyl lithium initiator.

Table 3. Sample calculations: Equal weights of monodisperse polymers. A = 50 000 g/mole; B = 100 000 g/mole; C = 150 000 g/mole.

Sample	Weight fraction of component			$\bar{M}_n$	$\bar{M}_w$	$\bar{M}_w/\bar{M}_n$
	A	B	C			
I	0.50	0.50	0.00	66 667	75 000	1.125
II	0.33	0.33	0.33	81 818	100 000	1.222

a hallmark of near monodispersity. Table 3 summarizes calculations performed on distinctly bimodal and trimodal systems. The calculated values of $\bar{M}_w/\bar{M}_n$ are 1.125 and 1.22 and will suggest to some a suitably narrow chain-length distribution. However, the SEC chromatographs calculated for these mixtures illustrate the unacceptable character in the molecular-weight distribution; see Fig. 6. In light of the potentially deceptive nature of $\bar{M}_w/\bar{M}_n$ ratios, examples of SEC data must be presented to verify near monodispersity. The term *narrow molecular-weight distribution* must be limited to polymers with $\bar{M}_{z+1}/\bar{M}_z$, $\bar{M}_z/\bar{M}_w$, and $\bar{M}_w/\bar{M}_n$ ratios of <1.05.

A final example of the fallacy of relying only upon an $\bar{M}_w/\bar{M}_n$ ratio as an indicator of monodispersity is given for the polyisobutylene sample of Fig. 7. This polymer, prepared by "living" polymerization, has bimodal character coupled with a high-molecular-weight component. The measured $\bar{M}_w/\bar{M}_n$ value of 1.11 fails completely in being a quantitative description of the distribution profile of that particular material.

Clearly, the mere comment, which is often encountered, that anionic polymerization was used to prepare the polymer in question is an inadequate pedigree. Reaction conditions must be described and their limitations understood. The companion information needed, as has been noted, is proper characterization.

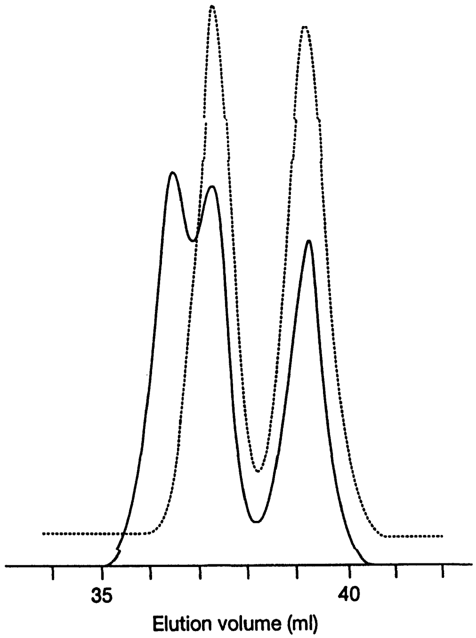

FIG. 6. SEC chromatographs of the polymer mixtures of Table 3; sample I (·······) is bimodal and sample II (———) is trimodal (after Fetters and Thomas, 1993).

2.2 Functionality and Architecture

Unfortunately, many of the functionalization reactions that have been described are not well characterized, as is discussed in a

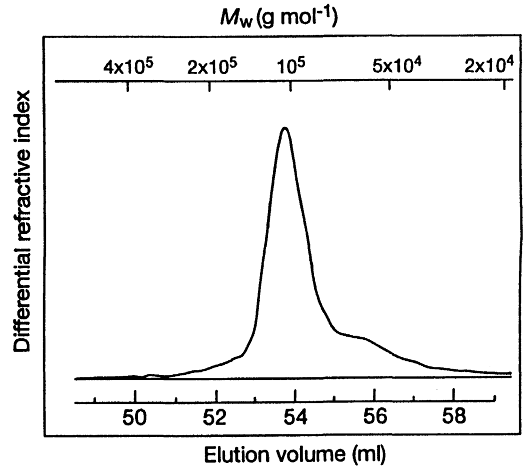

FIG. 7. SEC chromatograph of polyisobutylene standard prepared by a "living" polymerization (after Fetters and Thomas, 1993).

recent detailed review by Quirk (1992). Precedent from the reactions of model small-molecule analogs is often misleading. Thus, adequate, and necessary, characterization probes embrace chain molecular weight, functional group titration, NMR, UV-visible, and FTIR spectroscopy, thin-layer and column chromatography, and chemical reactions. The primary need in chain-end characterization is an accurate evaluation of functionalization efficiencies. To this end, knowledge of functional-group titration, spectroscopic probes, and chemical reactions can all contribute to determining the efficiency of a given reaction. Chromatography has proven useful (see, for example, Quirk and Yin, 1992) for analyzing unfunctionalized polymer mixed with the functionalized product as a consequence of the different migration rates that the two species exhibit. Chain molecular weight, when combined with these techniques, allows a quantitative assessment of the functionalization reaction in question.

As noted earlier, a high-resolution SEC column arrangement must be in place if meaningful distribution profiles are to be obtained. This is particularly true for the case where sequential monomer addition, chain coupling, linking, or branching can occur either intentionally to form complex architectures or unintentionally, as during polymerization or via a post-polymerization event. AB, ABA, or ABC block polymers are simple examples of the former. Accurate insight into the efficiency and success of each step in the preparation of these multicomponent systems can, and must, be evaluated by high-resolution SEC. This is shown in Fig. 8, where a poly(styrene-isoprene) diblock (Quirk and Lee, 1992) and the polystyrene segment (polymerized first) are shown. The lack of a signal for homopolystyrene in the SEC of the diblock clearly demonstrates that the resulting diblock is free of the homopolystyrene contaminant.

An example of unintentional chain coupling occurs in the presence of oxygen during the termination event (Fetters and Firer, 1977). As has been shown, inadequate SEC resolution will miss the presence of such coupled products (Ambler *et al.*, 1977). A similar situation can be encountered in functionalization reactions. For example, the carboxylation of poly(styryllithium), PS^-Li^+, in benzene using high-purity CO_2 at atmospheric pressure,

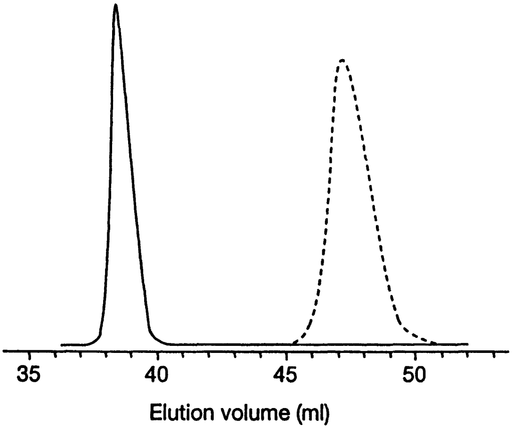

FIG. 8. SEC chromatographs of a poly(styrene-isoprene) diblock (—) and the polystyrene segment (---------) (after Quirk and Lee, 1992).

$$PS^-Li^+ + CO_2 + H_3O^+ \rightarrow PS\text{—}CO_2H + Li^+ + H_2O, \qquad (12)$$

produces the carboxylated polymer, PCO_2H, in only 46–66% yield. However, the contaminating products include the dimeric ketone, P_2CO (25–30%), and the trimeric alcohol, P_3COH (7–24%). Procedures that virtually eliminate the ketone and alcohol components have been developed and presented (Quirk and Yin, 1992; Quirk *et al.*, 1992). The presence of the trimeric alcohol and the dimeric ketone is shown in Fig. 9, with the former component unresolved by the μ-Styragel SEC column arrangement. The higher-plate-count ultra-Styragel column set reveals the presence of that branched component.

3. MODEL POLYMERS IN POLYMER PHYSICS

3.1 Morphology

There are many examples of the use of model polymers to develop novel materials structure. Rational control of microstructure is a particular challenge in polymers, in that one needs to control packing at several length scales simultaneously. Furthermore, each molecule has an enormous number of

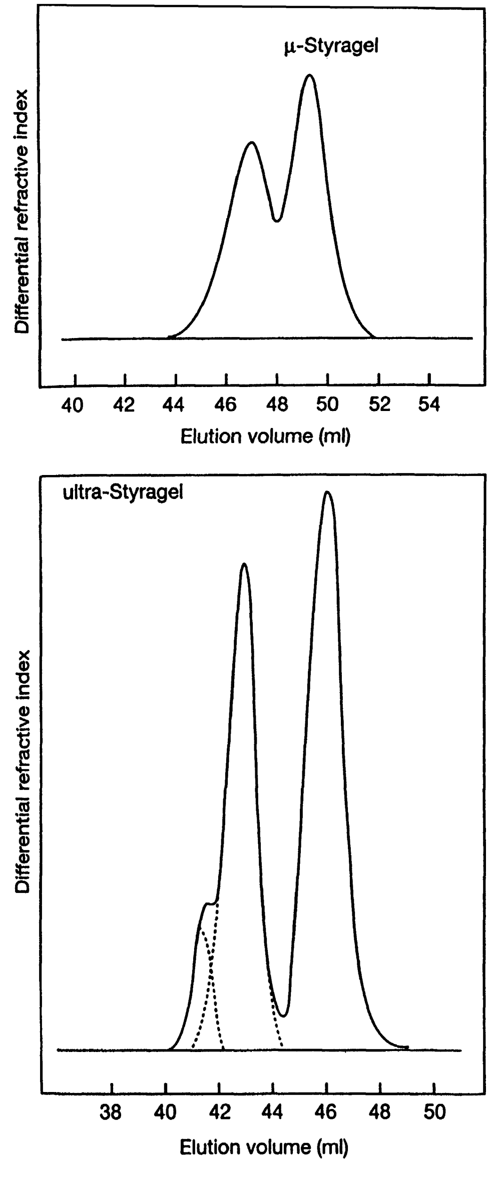

FIG. 9. SEC chromatographs of trimodal polystyrene evaluated by a μ-Styragel set and an ultra-Styragel set. The latter column arrangement reveals the presence of the three-armed star. (After Quirk *et al.*, 1989.)

structural states of similar energy from which to select, as a consequence of their inherent conformational diversity. As indicated, stereochemical and monomer sequence control during species synthesis is the essential aspect for molecular-level control of structure and function.

3.1.1 Crystallinity in Stereospecific Polymers The realization of desirable superstructures arising from the self-assembly of individual species far more complex than simple spheres requires intermolecular assembly to proceed in a uniform manner in order to allow the carefully built-in specificity of chain structure and the applied environmental conditions to produce the prescribed, desired structural state. With polymers, one discovers even with the most simple macromolecules a wide array of structural states and length scales; e.g., for semicrystalline linear polyethylene, the orthorhombic crystalline unit cell has edge lengths about 1 nm and the all-*trans* chains pack into lamellae typically 20 nm thick, which are separated by interlamellar noncrystalline regions wherein a combination of *trans* and *gauche* states results in a random chain structure.

Moreover, crystallization proceeds from nucleation centers to develop spherulites of average diameter of several microns. Inside a spherulite, the lamellae are radially arranged. Such a complex microstructural geometry involving both crystalline and noncrystalline phases makes establishment of structure–property relations difficult; furthermore, the important and practical study of the evolution of structure and physical properties with applied force or imposed strain is challenging both to characterize and to model. For this reason, simplified geometries and uniform structures have been produced to enable exploration of fundamental structure–property relations.

With the advent of synthetic schemes to produce stereoregular polymers, many polyolefins previously restricted to the amorphous state are now available in the semicrystalline state. These new polymers are rapidly becoming important thermoplastic elastomers with enhanced temperature stability and chemical resistance. However, studies of syndiotactic and isotactic polymers have frequently been hampered by the less than perfect configurational regularity of the materials. A prime example of what is possible with highly stereoregular polymers exists for syndiotactic polypropylene, sPP. The improved stereoregularity is the result of switching from vanadium-based catalysts (Boor and Youngman, 1966) to new metallocene catalysts based on Zr and Hf (Ewen *et* *al.*, 1988). These new catalysts have increased the percentage of racemic triads as measured by ^{13}C NMR from 77% to >99%.

More than 25 years of investigation of the less than fully syndiotactic material concluded that the chains formed $(t_2g_2)_2$ helices that pack isochirally in a face-centered unit cell. Recently, Lovinger *et al.* (1993) used x-ray diffraction, electron diffraction, and molecular modeling to identify the stable, high-temperature structure as a fully antichiral, face-centered unit cell (*Ibca* space group) of sPP. This new (and correct) unit cell has dimensions double that of the earlier unit cells. Furthermore, Lovinger *et al.* (1993) showed that the previously proposed models were the result of studying mixtures of syndiotactic and isotactic PP, as illustrated in Fig. 10. The incorporation of defects increases as the crystallizing temperature decreases, as evidenced by streaking of the *h*20 layer of the reciprocal lattice in electron diffraction. This streaking corresponds to a *b*/4 vacancy along the crystal-growth direction to produce isochiral packing. Work by other groups has confirmed these morphological findings, and studies are now underway to understand the structure–property relationships in sPP.

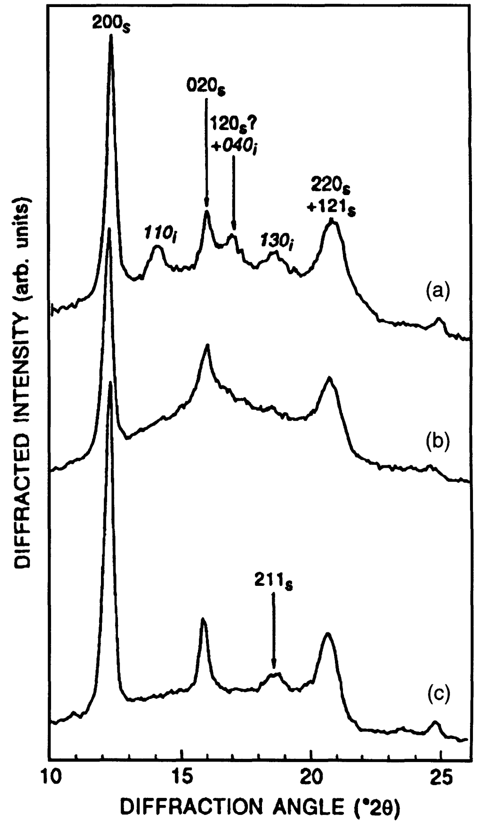

FIG. 10. X-ray diffractograms of (a) poorly syndiotactic polypropylene containing 77% racemic triads, typical of all previously studied sPP samples, (b) fully syndiotactic polypropylene as received, and (c) fully syndiotactic polypropylene crystallized isothermally at 135 °C. Subscripts *i* and *s* refer to isotactic and syndiotactic polypropylene, respectively. (After Lovinger *et al.*, 1993.)

3.1.2 Self-Assembly in Block Copolymers Self-assembly in block polymers produces microdomains composed of the respective blocks. Typical domain sizes are several hundred angstroms, and these domains, in turn, assemble into grains with typical diameters of several microns. The grains of the cylindrical or lamellar microdomain-forming block copolymer have a preferred orientation, resulting in local anisotropy of the material properties. However, since the grains are relatively small in comparison to the whole sample and since they are normally in random orientations, the resultant macroscopic sample exhibits isotropic properties. When such materials are examined by scattering or subjected to mechanical testing, the net response is the superposition of the different responses to each of the various grain orientations. Fundamental understanding of structure–property relationships is thus difficult to achieve.

To overcome such limitations, one can employ special processing to convert the isotropic multigranular sample into a single crystal. An applied bias field (mechanical, electrical, etc.) can result in materials with single-crystal-like texture. Such an approach was first taken by Keller and co-workers (Keller *et al.*, 1970; Folkes *et al.*, 1973), utilizing extrusion to produce highly oriented single-crystal-like material of a triblock copolymer. This process is akin to the texturing of polycrystalline metals by die drawing. While providing a highly oriented sample, this process suffers from the presence of grain-boundary structures and other morphological defects because the alignment process is initiated from an already microphase-separated material. The influence of such defects and boundaries is unknown at present, but in analogy to work with other materials, one can expect a strong influence on properties. Recently, Albalak and Thomas (1994) devised a roll-casting process that eliminates grain boundaries by causing the self-assembly of the block copolymer molecules into the microdomains to take place in an orienting flow field.

The roll-casting process is based on the rolling of an initially homogeneous polymer solution between two counter-rotating cylinders while removing solvent at a controlled rate. The experimental system is schematically pictured in Fig. 11 and consists of two adjacent rollers and is similar to the conventional setup of calenders or roll mills. The polymer solution flows between the rolls through a minimum gap, called the "nip," and coats either one or both of the rolls. The detailed velocity profile in such a geometry has been analyzed (Gaskell, 1950) and contains both shear and elongational flow components. The key to this process is that the onset of microphase separation occurs in the applied flow field so that the microdomains form in a globally oriented structure. Figure 12(a) is a TEM micrograph of a [0001] axial view showing the well-ordered microdomain structure of a PS/PB/PS triblock copolymer containing PS cylinders in the PB matrix. The perfection of the packing of the PS cylinders is quite evident. Low-magnification TEM images show that the single-crystal structure is unperturbed for at least many tens of microns. The degree of order over larger distances can also be assessed by small-angle x-ray scattering (SAXS). Figure 12(b) is a two-dimensional SAXS pattern taken with the incident beam along the [0001] direction. The pattern originates from a sample area on the order of 1 mm^2, demonstrating the single-crystal nature of the macroscopic film. Such specimens offer significant advantages to test phase-morphology and phase-transformation theories and to further the basic understanding of transport and chain dimensions in block-copolymer systems.

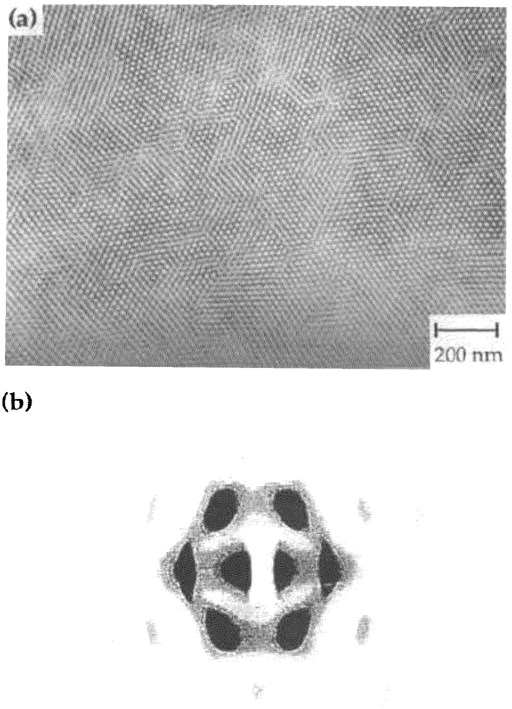

FIG. 12. (a) Bright-field TEM micrograph of an OsO_4 stained, microtomed section of a roll-cast PS/PB/PS film. View is along flow direction and shows the two-dimensional hexagonal lattice packing of the PS cylinders. (b) Two-dimensional small-angle x-ray scattering pattern of roll-cast PS/PB/PS film with incident beam along the flow direction. Bragg reflections of a well-ordered two-dimensional hexagonal structure are evident. (After Albalak and Thomas, 1994.)

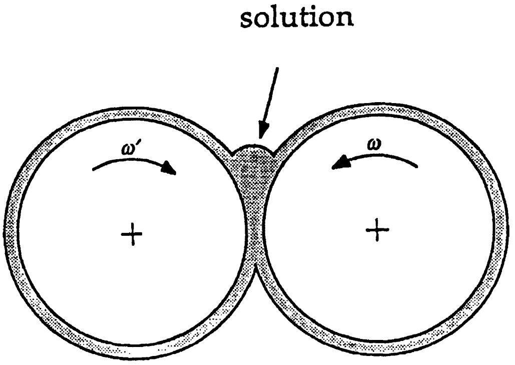

FIG. 11. A schematic representation of the roll-casting apparatus. A concentrated solution of block copolymer is processed between two adjacent counter-rotating cylinders. (After Albalak and Thomas, 1994.)

Model diblock copolymers produced by anionic polymerization and processed into single-crystal specimens are quite useful to probe how the microstructure influences chain dimensions. SAXS and small-angle neutron-scattering (SANS) measurements, as well as theoretical predictions of the domain spacing in A/B amorphous/amorphous block copolymers, indicate that the spacing varies approximately as $M^{2/3}$ in the strong-segregation regime where the individual phases are essentially pure components and the A/B junction is strongly localized in the narrow interfacial region between domains. The individual component block dimensions will therefore be distorted from the Gaussian behavior of a chain in a single-phase melt, where R_g scales as $M^{1/2}$. Measurement of the chain dimensions in a phase-separated block copolymer is, however, complicated by the strong scattering from the periodic domain microstructure, which occurs in the same angular range as the single-chain scattering.

Recently, Matsushita *et al.* (1990) used anionic synthesis to carefully deuterium label *parts* of a block. The selective use of perdeutero monomer provides neutron contrast so as to examine the dimension of a particular portion of the chain with SANS. Two types of triblock copolymers composed of deuterated PS, PS, and poly(2-vinylpyridine) (PVP) were prepared: "end labeled" (dPS-PS-PVP) and "centered labeled" (PS-dPS-PVP). Such studies permit the evaluation of polymer chains in a polymer melt environment. Lamellar orientation resulted from the solvent casting process rather than by shearing. The center portion of the chain adjacent to the A/B diblock junction was found to be contracted along the direction parallel to the interface to the same extent as previous researchers had found for the entire block (i.e., approximately 70%). The portion of the chain at the free end of the block was localized in the middle of the PS domain, and its dimension was unperturbed by the microdomain morphology. Thus, the gradient in chain stretching can be explored in microstructured systems.

3.2 Polymer Dynamics in the Melt

There are many examples of the use of model polymers to evaluate theoretical concepts in polymer physics. Here we detail the employment of model polymers in testing the elegant reptation hypothesis of de Gennes, Doi, and Edwards and the tube concept in reptation (de Gennes, 1990; Doi and Edwards, 1986). According to reptation theory, individual chains are assumed to be constrained by their neighbors and are thus compelled to migrate primarily along their own contours in a snakelike manner. Thus, a polymer melt is made up of an assembly of chains all simultaneously involved in disengagement from their current cage of strands. In this disentanglement process, each chain creates a new cage and configuration as it undergoes its movement through the mesh. The cage can be visualized as a tube of diameter d and contour length l, which encloses each chain in the mesh. The chains are assumed Gaussian, with v chains per unit volume. (Gaussian behavior of polymer molecules is discussed more fully in the next section.) The tube diameter is independent of molecular weight M, while the tube contour length is directly proportional to the molecular weight.

The distance between entanglements, d_t, is expressible in terms of the measurable properties as

$$d_t^2 = 0.8\left(\frac{\langle R^2\rangle_0}{M}\right)\left(\frac{R_gT}{G_N^0}\right), \tag{13}$$

where $\langle R^2\rangle_0$ is the square of the end-to-end distance of the polymer, G_N^0 is the plateau modulus (the short-time modulus of an entangled polymer liquid), R_g is the gas constant, and T is the absolute temperature. The above equation can be reduced to

$$d_t^2 = 0.8[\langle R^2\rangle_0/M]M_e, \tag{14}$$

where M_e denotes the entanglement molecular weight that is determined from the plateau modulus (Doi and Edwards, 1986). Thus, a combination of the static- ($\langle R^2\rangle_0/M$) and the dynamic-based (M_e) parameters allows an evaluation of d_t. Until recently, the *direct* measurement of d_t had not been accomplished.

For that purpose, nearly monodisperse, amorphous poly(ethylene-propylene) (PEP) was used (Butera *et al.*, 1991; Richter *et al.*, 1992). The route to that polymer was via the hydrogenation saturation of anionically prepared polyisoprene. The analytical tool of choice was the IN-11 neutron spin-echo (NSE) spectrometer at the Institut Laue-Langevin in Grenoble. The unique feature of the NSE technique is its ability to evaluate in a direct way the energy changes induced in neutrons during the scattering process. In essence, the dynamic data are gathered by examining the decay in an NSE as a function of an imposed precessional frequency. Therein, a magnetic field of varying strength is applied to the incident polarized neutron beam. The small energy change of each scattered neutron is analyzed as a shift in the precessional phase. In view of the limited time resolution (ca. 4 × 10^{-8} s) and distance resolution (5–100 Å) of the IN-11 instrument, only the most dynamically flexible chains with rapid local motion are candidates. PEP and polyethylene (from the saturation of 1,4-polybutadiene) fulfill these criteria.

The results of such an NSE investigation on PEP are summarized in Fig. 13, which also contains rheological and SANS findings. The tube diameter (NSE) was found to increase with temperature, while the radius of gyration (SANS) and plateau modulus (rheology) were observed to decrease. The plateau modulus also signaled an increase in the entanglement molecular weight, which, when combined with the change in chain dimensions, led to an increase in the tube diameter with increasing temperature. It is important to note that the values of d_t determined by various techniques were in essential agreement, a picture also found for polyethylene (Richter *et al.*, 1992). These results fortify the elegant *Ansatz* of de Gennes's reptation model.

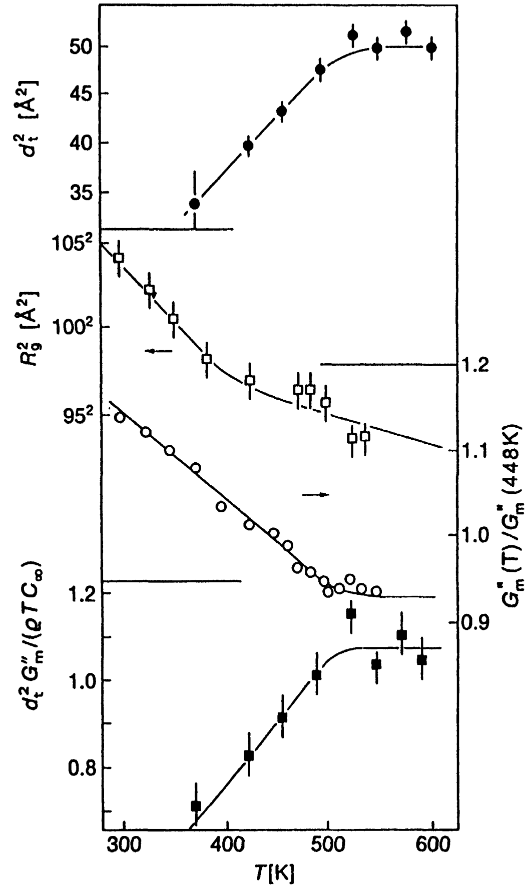

FIG. 13. Entanglement distance d_t, radius of gyration R_G^2, ratio of G''_m to G''_m (448 K), and $d_t^2 G''_m/rTC_\infty$ for alternating poly(ethylene-propylene) as a function of temperature, where G''_m is the maximum in the shear loss modulus of the entanglement network (after Fetters and Thomas, 1993).

3.3 Chain Conformations in Solutions

As mentioned in the previous section, Gaussian statistics are used to describe the dimensions of a polymer chain. Such random-walk statistics imply that each step of the process (i.e., along the polymer chain) is of the same length and fully independent of all other steps. The simplest application of Gaussian statistics to polymers uses the length of a monomer unit, l, and the number of monomer units, $N_w = M/M_0$, where M_0 is the molecular weight of a monomer unit and end effects are neglected. In this case the square of the end-to-end distance of the polymer chain is $N_w l^2$. A more realistic approach includes the bond-angle and bond-rotation restrictions associated with the chemical structure of the polymer chain, which add prefactors to the expression. In lieu of these structural details, the short-ranged steric hindrances can be accounted for by defining a statistical segment length a to be the step length of a random walk, such that the unperturbed square of the end-to-end distance is given as

$$\langle R^2 \rangle_0 = N_w a^2. \tag{15}$$

Experimentally, the statistical segment length is determined by measuring the radius of gyration R_g, using a scattering technique and applying the expression

$$a^2 = 6\langle R_g^2 \rangle / N_w, \tag{16}$$

where $\langle R_g^2 \rangle = \langle R^2 \rangle_0 / 6$, which is an exact solution for a random walk. The characteristic ratio, C_∞, describes the stiffness of a polymer molecule, which is associated with fixed bond angles and short-range steric hindrances and is defined as $\langle R^2\rangle_0/N_w l^2$. The short-range modifications to the random walk are sufficient when the polymer–polymer and polymer–solvent interactions are equivalent, that is, in the θ condition. The θ condition or theta condition refers to a specific combination of polymer, solvent, and temperature in which the polymer chain exhibits Gaussian behavior. Otherwise, longer-ranged interactions, which give rise to excluded-volume effects, need to be incorporated, and Gaussian statistics fail.

Flory (1953) was the first to predict that chain dimensions in a θ condition are identical to those in a polymer melt and that the chain behaves like an ideal random walk. This prediction has been confirmed by SANS and other techniques. Another prediction, the rotational isomeric state (RIS) prediction, involves the interdependence of the chain conformation and the bond-rotation angle. Rather than assign a finite probability to all possible bond-rotation angles as defined by four backbone atoms, the RIS prediction restricts the bond-rotation angle to three discrete values. A probability is assigned to each of the three values, which ignores the possibility that severe steric interactions do occur for certain sequences of bond angles. The use of model polymers has been of great value in the detailed evaluation of RIS predictions pertaining to the polymer chain dimensions and their respective temperature coefficients. The advent of SANS has expanded the range of these evaluations, because both parameters can be measured in the melt state. Some recent findings are presented in Table 4.

The combined results from light scattering in the θ condition, RIS theory, and SANS in the melt show excellent agreement with regard to the parameters in question for PE and PEP. However, such agreement is absent for *a*-PP and *a*-PEE. It can be seen that neither RIS theory nor θ-condition measurements yield chain-dimension temperature coefficients that may be related to what is observed in the melt state. From the RIS standpoint there seemingly is a problem in correctly visualizing the role of nonbonded interactions as a function of temperature. The failure of the RIS approach is duplicated in the failure of the θ-condition results to mimic melt behavior. Thus, the assumption that modeling a polymer in a vacuum universally yields its behavior under θ conditions, which in turn serves as a mimic of melt behavior, is erroneous. Solvent influences on "unperturbed" chain dimensions have been previously predicted (Lifson and Oppenheim, 1960). Our current understanding lacks predictive capacities regarding which solvents can exert so-called specific solvent effects, or, conversely, which polymers are susceptible to such influences. Nonetheless, a partial rationalization as to why solution θ condition is not equivalent to melt behavior is possible.

Rotational isomeric states are identified with the minima of the conformational energy maps, minima that can be influenced by local-polymer solvent interactions—the so-called "specific solvent effect." This effect can be viewed as one that does not create

Table 4. Polyolefin chain parameters at 298 K.

	$R_g/M^{0.50}$ (Å mol$^{0.50}$ g$^{-0.50}$)		C_∞		a (Å)		$d \ln\langle R^2\rangle_0/dT$ (10^3/deg)		
Polymers	LS	SANS	LS	SANS	LS	SANS	LS	SANS	RIS
PE(PEB-2)	0.470	0.485	7.9	8.4	6.1	6.3	−1.1	−1.15	−1.2
PEP	0.381	0.397	6.5	7.1	5.6	5.8	−1.1	−1.16	−1.0
a-PP	0.340	0.337	6.6	6.1	5.6	5.3	−2.9	−0.1	0 to −1.8
a-PEE	0.279	0.283	5.5	5.7	5.1	5.2	−2.3	0.4	−0.1

PE = polyethylene; PEB-2 = poly(ethylene-butene) with ca. 2 ethyl branches per 100 backbone carbons; PEP = alternating poly(ethylene-propylene); a-PP = atactic polypropylene with Bernoullian chain statistics; a-PEE = atactic poly(ethylene ethylene) with Bernoullian chain statistics. LS = solution light scattering. SANS = small-angle neutron scattering of melt. RIS = rotational isomeric state (theory).

new rotational isomeric states but modifies the potential energy of those already existing in the melt. Thus, the locations of the various minima remain unchanged while their magnitudes can be altered by the prevailing solvent–polymer interaction for any particular state.

This scenario requires that the probabilities of occurrence of the most stable conformations—those isomeric states required by the short-range intramolecular interactions—can be modified by solvent interaction. Under theta conditions such short-range interactions can be neglected *if solvent discrimination between conformations is absent.* This criterion is apparently met for polyethylene and alternating-poly(ethylene-propylene) copolymer (Table 4). Conversely, the difference between the solution and melt behavior for *a*-PP and *a*-PEE seemingly demonstrates that their local conformational characteristics are considerably influenced by theta-solvent (*n*-alkyl alcohols) interactions, interactions that lead to enhanced *gauche* populations with increasing temperature (and hence a negative temperature coefficient for chain dimensions). It appears that the configuration of the skeletal bonds will lead in some cases to solvent discrimination regarding the attached side groups with *gauche* sequences being more susceptible to such interactions than their *trans* counterparts. Given the presence of such favorable interactions, the net effect is a decrease in the *trans/gauche* ratio with increasing temperature.

Similar behavior is evidenced for *a*-PP in either 2,4-dimethyl heptane or 2,2,4-trimethyl-pentane, which gave a $d \ln\langle R^2\rangle_0/dT$ of -2.4×10^{-3} deg^{-1} over the temperature range of 10–70 °C. The use of those alkanes was based on their assumed capacity to act as athermal solvents, an assumption that the SANS work has shown to be incorrect. Interestingly, like the *n*-alkyl alcohol theta solvents, these branched alkanes alter the *a*-PP *trans/gauche* ratio with increasing temperature. The solution-induced behavior of *a*-PP and *a*-PEE is strikingly different from that observed in the melt, where the former is found to exhibit a virtually invariant population of conformer types, while the latter shows that increasing temperature favors the *trans* sequences.

Attempts have been made to account for solvent effects within the framework of the RIS model (Brant and Flory, 1965; Bahar *et al.*, 1986; Yoon *et al.*, 1975). This involved the adoption of a truncation procedure involving an adjustable parameter, *s*, which Brant and Flory (1965) took to be the sum of the van der Waals radii of the interacting atoms. Variations of this approach have subsequently led to a procedure (Bahar *et al.*, 1986) that does not utilize adjustable parameters. However, although *a*-PP and *a*-PEE apparently acquiesce to the influence of their solvent shells, the nature and identity of these local interactions are not generally understood (Janik *et al.*, 1987).

The foregoing SANS studies were facilitated by small heterogeneity indices of the subject polymers. Thus, the measured R_g (z-average–dependent dimension) is equal to the weight-average value. In other words, polydispersity corrections are unnecessary.

GLOSSARY

Chain Transfer: The active site at a chain end that propagates during chain polymerizations transfers to a monomer, solvent, initiator, or impurity molecule in the reaction medium.

Configuration: Distinct polymer molecules, typically referring to a specified arrangement of substituent groups along the backbone. Different configurations are delineated by the tacticity and sequence distribution of the polymers.

Conformations: Distinct three-dimensional shapes of a polymer molecule as accessed by rotating around backbone atoms. A Gaussian conformation is a conformation that obeys random-walk statistics.

Copolymer: A polymer having two or more monomer units within the polymer molecule. The relative amounts and the sequence (random, alternating, block, etc.) of these different monomers need to be specified to define the copolymer fully.

Mikta-Arm Polymer: A three-arm star molecule in which each arm contains a different monomer repeat unit.

Model Materials: Materials for which the parameters of molecular characterization are very well represented by the ensemble average.

Molecular-Weight Distribution: The relative amounts of the different molecular-weight polymers in a single sample.

SANS: Small-angle neutron scattering. Contrast for these experiments is typically provided by using perdeutero monomer or by saturating carbon–carbon double bonds with deuterium or a mixture of deuterium and hydrogen.

Size-Exclusion Chromatography: An experimental tool to evaluate the molecular weight and molecular-weight distribution of polymers as compared to standards (typically polystyrene).

Tacticity: Distinct polymer configurations for polymers with the monomer type CH_2—CXY, where X and Y are substituent groups. See Fig. 3 for an illustration of isotactic, syndiotactic, and atactic polymers.

Terpolymer: A polymer having three monomer units within the polymer molecule. The relative amounts, sequence (random, alternating, block, etc.), and architecture (linear, star, etc.) of these different monomers need to be specified to define fully the copolymer.

Theta Condition: The specific condition of polymer, solvent, and temperature at which the polymer chain behaves according to Gaussian statistics and the polymer–polymer interactions are enthalpically equivalent to polymer–solvent interactions.

INTRODUCTION

The main focus of this article is the study of *micromechanical devices,* defined as precision micromachines built by microelectromechanical technologies in the size range between a micrometer and a millimeter. The roles of these types of machines and the underlying science on which they are based are discussed in Sec. 3. Other interdisciplinary aspects specific to micromachine design and fabrication technologies are described earlier, in Sec. 2. Some of the technological challenges that the next frontier of submicron devices face are addressed in Sec. 4. The final section of the article discusses the present-day status and the future prospects of micromechanical devices.

1. GENERAL PRINCIPLES AND OVERVIEW OF MICROSYSTEMS TECHNOLOGIES

The relatively recent development of microelectromechanical devices—or simply microsystems, as they are also referred to—crosses many conventional borders of different disciplines of science and technology. Indeed, microsystems research has become a model of the modern interdisciplinary efforts that have gained such prominence in the past two decades. Silicon fabrication techniques have been the real foundations of microsystems, and many impressive devices have been fabricated by direct adaptation of microelectronic techniques into this field. Many other techniques, such as surface mi-

cromachining and LIGA processes (see Sec. 2.3) have developed new capabilities to enhance further the versatility of semiconductor technology. It is the richness of different ideas and techniques that makes the microelectromechanical field so dynamic.

1.1 Historical Perspective

The historical development of microelectromechanical technologies can be viewed in three stages. First, each specific technology based on mechanics, electronics, optics, information, and physical sciences developed independently. Machine systems were quite independent of electronics technology at this earlier stage (see MECHANICAL INSTRUMENTATION). However, with the rapid progress of sensors and processors brought by the microelectronics revolution (see MICROELECTRONICS), the relationship changed, resulting in the development of truly electromechanical systems, thus creating the interdisciplinary field of mechatronics. This second stage witnessed the parallel combination of optics and electronics into what is now widely known as optoelectronics (see QUANTUM OPTOELECTRONIC DEVICES). Furthermore, the recent developments in optical technology, especially semiconductor lasers and advanced lithography, are now allowing the beginning of a third stage, where complete technology fusion is bringing these fields to merge fully in the new field of optomechatronics. New physical frameworks such as micromechanics, microdynamics, or even photomicrodynamics appear at this point (Ukita *et al.*, 1993).

These developments can be described by the chronological emergence of new technologies. As shown in Table 1, process automation started in the early 1960s. In the late 1960s mechanical automation started making use of electronic control technology. In the early 1970s the age of mechatronics was in an embryonic stage and grew into a mature discipline in the late 1970s, when the use of integrated circuits (ICs) with large-scale integration capabilities became widespread. In the meantime, the semiconductor laser, which had been developed in 1962, became able to emit light continuously at room temperature in 1979. This resulted in the birth of optomechatronics, which combines mechanics, electronics, and photonics, during the early 1980s. In the late 1980s, with the use of advanced semiconductor-device fabrication technologies, microsystems were actively studied. New kinds of microsensors and microactuators became feasible. In addition, novel probing techniques such as the scanning tunneling microscope (STM) and atomic force microscope (AFM) have greatly advanced our knowledge of microscopic mechanisms to the molecular and the atomic levels. Thus, in the 1990s the fusion of information and energy technologies has started, as a prelude to the first stages of molecular nanomachines.

Table 1. Chronology of microsystems technology developments.

Years	Development of technology and new trends
1960	Process automation in chemical industry and heavy machine industry
1965	Mechanical automation by electrical control
1970	Early stage of mechatronics that makes use of IC and LSI
1975	Mechatronics using microprocessors
1980	Optomechatronics using semiconductor lasers
1985	Micromechatronics using process technology
1990	Age of mechatronics that achieves fusion of information and energy

1.2 Categories of Systems Technologies

A conventional precision machine usually consists of a main body and many components. Therefore, specific design, fabrication, and measurement technologies are necessary to assemble all these pieces together in a systematic way. According to their size dimension, machines are usually classified in three categories: millimeter, micrometer, and nanometer machines. Although there is no obvious abrupt transition between these arbitrarily defined types, each broad category uses different materials and has a distinctive set of systems technologies. The millisystems use metals, polymers, or ceramic materials. Various ultraprecision methods such as discharge and beam processes, as well as bulk etching, are employed to approach the miniaturization limit of these conventional precision machines. The microsystems are based on modified semiconductor fabrication technologies such as wafer bonding and advanced photolithography, which can be applied to silicon, gallium arsenide, and thin-film materials. In the new frontiers of miniaturization, nanosystems usually consist of macromolecules such as proteins or other organic polymers in which matter is manipulated at the molecular and the atomic levels.

2. INTERDISCIPLINARY APPROACHES TO MICROSYSTEMS TECHNOLOGIES

As we have underscored, the design and fabrication of micromechanical systems requires wide exchange of information and joint efforts from researchers in many divergent fields of science and engineering. In this section we emphasize those interdisciplinary aspects of microsystems technologies that are of special importance for the successful development of microelectronic mechanical devices.

2.1 Microenergy Systems

The relentless pace of miniaturization is forcing drastic changes in the way electronic systems are built. As more compact and larger numbers of components with high-level functions are built in ever-shrinking dimensions, interconnections, packaging, and assembly become increasingly complex and important aspects of the fabrication process. Among other effects, this is motivating designers to rethink drastically how to power such systems (Govindarajan and Forrest, 1991). Local autonomy from a central power supply becomes a highly desirable feature to avoid excess power dissipation, high-frequency crosstalk between adjacent elements, and the general reliability problems associated with ultrahigh-density systems. Having distributed microenergy capabilities also becomes more feasible as the energy level required to perform complex electronic or electromechanical functions on such small scales decreases accordingly. To achieve this goal, three main aspects will require much attention in the years to come, namely, the power generation, the energy storage, and the power supply of microenergy systems.

There are several approaches to the power generation in microsystems, depending on the nature of the energy source employed. Electrical power can be obtained from optical, mechanical, or thermal sources using light, pressure, or infrared sensors, respectively. For instance, photovoltaic, microwave, and infrared devices can generate electrical currents from optical, microwave, and infrared radiation absorption existing within or externally supplied to the environment. The electrical energy thus generated can directly power different microelectromechanical functions or be stored by a microstorage battery system for later use. Mechanical pressure sensors, accelerometers (Allen *et al.*, 1989), and flow-measurement microdevices (Cho *et al.*, 1989) are rapidly emerging with enhanced sensitivity and high-precision capabilities. Vice versa, electrostatic micromotors that convert electrical signals into mechanical motion have been successfully fabricated from thin-film technologies compatible with silicon processing (Fan *et al.*, 1988), as described in Sec. 3.

The development of power-integrated technologies has brought the ability to provide the interface between digital control logic and the power load (Baliga, 1990). Thus, power ICs monolithically integrate power control with sensor and logic-circuit functions. This interface allows the intelligent use of power in microelectronic systems and micromachines. Smart-power technology combines complementary metal-oxide semiconductor (CMOS) logic, high-performance bipolar analog circuits, and high-voltage power devices all on the same chip. Indeed, smart-power chips can perform load monitoring, diagnostic functions, self-protection, and information feedback to a microprocessor, in addition to handling large amounts of power to the load. This allows highly efficient energy management in a variety of microelectronic systems by connecting a distributed network of smart power supplies with a multiplexed bus. One of the most critical elements in such a system is the power switch, which is usually a metal-oxide-semiconductor field-effect transistor (MOSFET) or MOS/bipolar device depending on the current-handling levels required. The main advantages of power MOSFETs over bipolar power transistors are the paralleling capability, high switching speed, high input impedance, and superior safe operating area

(Baliga, 1991). For the realization of ultracompact power supplies, high-frequency switching is essential in order to reduce the size of other electronic and magnetic components to provide full integration, as shown by Mino *et al.* (1992) (see MICROMAGNETICS). Thus, low capacitance and ultralow "on" resistance are critical requirements of advanced power MOSFET design (Vera *et al.*, 1992).

One area that has yet to produce significant progress is that of microenergy storage. Indeed, in terms of the energy that batteries store for a given size and weight, not much improvement has been achieved. For example, today's nickel-cadmium batteries are only about 40% more effective than the first ones about 100 years ago. Lithium-based batteries provide about two or three times the energy of standard nickel-cadmium or lead-acid cells (Yotsumoto, 1992), as shown in Fig. 1. However, the lithium metal is highly reactive, and some associated safety concerns that have prevented their extensive use remain among the most important problems to be solved. Thin-film batteries are of great interest for their potential use in monolithically integrated electromechanical systems. A rechargeable microbattery that could power a single chip, or even single electronic components within, would have a significant impact on the development of advanced electromechanical devices. Preliminary steps in that direction have been taken by Li *et al.* (1992), who have reported a nanometer-scale electrochemical cell built using an STM to deposit silver and copper pillars electrochemically on a graphite substrate.

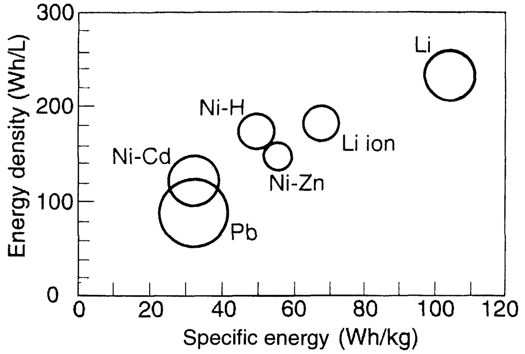

FIG. 1. Energy density in battery systems (Yotsumoto, 1992).

2.2 Microdesign Methods: CAD

Over the last decade, we have observed dramatic progress in the development of computer-aided design (CAD) tools for ICs. Indeed, the ever-increasing computational power has allowed the development of extensive numerical codes that perform very sophisticated calculations at relatively low cost. These advanced CAD capabilities have had a tremendous impact on the development of very large-scale integrated (VLSI) and ultra-large-scale integrated (ULSI) technologies because they have allowed the full simulation of a wide range of electronic systems at the process, device, and circuit levels. The virtual fabrication and testing of complex electronic systems in a computer environment makes it possible to bypass the real implementation of all but the optimal electronic structures, with significant savings of resources and time. However, most unfortunately, many of these tools are of limited applicability to the design of microelectromechanical systems.

Although microelectromechanical systems are usually fabricated using refinements of the planar photolithographic techniques used in the IC industry, they require very different CAD tools than those used by the IC designers because of their intrinsic three-dimensional (3D) nature. The most important requirement that such a microdesign CAD system should have is to be able to analyze realistic 3D structures whose geometry is directly provided or derived from a fabrication process simulation that uses a process flow chart and mask-level description. Since 1987, several research groups have reported some progress in this area. Koppelman (1989) has created a program that gives a 3D solid-geometric model from the IC process description and mask data. Crary and Zhang (1990) and Zhang *et al.* (1990) have developed an overall user interface that can access modules simulating the mechanical behavior of specific structures. Senturia (1987) has addressed both the system and the specific tool-development levels.

However, all these approaches must satisfy some rather stringent requirements. For instance, they must work from the actual design. Usually, IC CAD does not provide tools for automatic generation of 3D models that are needed for subsequent mechanical and electrical analysis. Hence, the structure simulator link between the IC layout and fabrication process world and the three-dimensional model is an essential feature of microelectromechanical CAD systems. Simulation typically involves finding solutions for quantities not only in the interior but also in the exterior of the structures. It is possible to use finite-element modeling methods to analyze both interior and exterior problems. However, this can be computationally very demanding. Consequently, sometimes accelerated boundary-element procedures that require only surface and interior meshes are employed (Conti *et al.*, 1991). Despite recent progress, generation of a satisfactory 3D volume mesh shape from a boundary representation is still an open question.

The long-term aim should be to provide a structure simulator with great geometric flexibility as well as effective links to general 3D analysis tools within the same computational environment. Maximum portability and compatibility with existing IC CAD tools is of utmost importance in any microelectromechanical CAD system. Thus, a structure simulator needs to interface with independent mechanical and electrical modeling software packages. Many specific implementation decisions must be made in the early stages of a system development in order to guarantee an architecture that permits the substitution of different software models. To achieve this degree of flexibility, an object-oriented architecture is most convenient because it can use the same data structure regardless of the specific data type as long as the type can be recognized and evaluated by the user interface (Shulman *et al.*, 1991). Following this approach a structure simulator can merge the mask layout and process information with the construction of a 3D solid model whose mechanical as well as material and electromagnetic properties can then be simulated by independent modules well integrated into a complete microelectromechanical CAD system that can perform comprehensive design, analysis, and test functions.

2.3 Microfabrication Process Technologies

With the recent surge of available microactuators in addition to the steady improvement of microsensors and interface circuitry, many of the elements for the development of complete integrated microsystems appear to be in place. Accordingly, there have been many proposals for the creation of such systems with a wide range of applications (Minami *et al.*, 1993). These range from microrobots for medical and several other applications to sophisticated control or positioning systems of great accuracy. If the proponents are successful, the coming years should witness the practical realization of multiple structures merging mechanical, thermal, electromagnetic, and optical components on a common substrate. Advanced assembly, interconnections, and packaging techniques will be particularly crucial to the cost-effective implementation of such schemes.

Many research groups around the world are intensively developing a variety of microfabrication technologies for a diverse number of applications. Most of them are inspired by or derived from the vast pool of know-how accumulated during the past decades of explosive growth in the microelectronic industry. However, translating IC-based technologies for micromachine fabrication sometimes is neither possible nor advisable. Thus, creatively adapting these technologies or attempting completely new approaches is of great importance for the development of this emerging field.

Micromachining was born in the 1960s when precise silicon etching techniques were first developed in the early stages of ICs (Lepselter, 1966). The initial work was based on isotropic etchants, which were straightforward to use but difficult to control. Later, anisotropic etchants that make highly directional and reproducible etching possible allowed significant progress in selective control. By and large, they are the basis of micromachining today. With the use of photolithography, an etch mask is defined on the back of the wafer, aligning it with patterns on the front surface. The wafer bulk is then selectively etched from the back. The existence of impurity-based etch stops in silicon has allowed micromachining to become a high-yield production process in the past decade (Petersen, 1982). A well-known example of this technique is the wide use of heavily boron-doped (p^+) silicon with ethylene diamine pyrocatechol (EDP) as anisotropic chemical etchant for the fabrication of diaphragm or beam sensors. Indeed, bulk micromachining has been so far the widest used technique for most integrated sensors produced by industry (Yoon and Wise, 1990). However, this method requires very long times to etch the silicon substrate from the back, usually several hours. An approach to overcome this serious limitation that has recently gained much acceptance is surface micromachining (Howe, 1988).

Surface micromachining utilizes a number of thin-film technologies. This technique has been used to fabricate various microstructures, including resonant microsensors and electrostatically driven micromotors (Fan *et al.*, 1988). In this method, a sacrificial layer (usually silicon dioxide or silicon nitride) is initially deposited and patterned on a silicon wafer. Next, the film for the desired microstructure is deposited and patterned as well. The sacrificial layer is then etched, leaving the undercut microstructure freely suspended but connected to the substrate through those areas beyond the patterned sacrificial layer. Several research groups have demonstrated the significant potential of this technology. Howe and Muller (Howe and Muller, 1986) fabricated a resonant vapor sensor with a free-standing polysilicon bridge. Rotary micromotors have been developed by Mehregany *et al.* (1990), Bart *et al.* (1990), and Flynn *et al.* (1992), among others. Resonant microsensors can be easily fabricated with this technique, and a wide range of accelerometers, pressure sensors, and microactuators are currently under development for automotive and consumer electronics. The successful development of surface-micromachined micromechanical structures has been made possible by the progress in understanding the mechanical properties of thin films that are crucial for the fabrication of devices with free-moving parts (Suzuki *et al.*, 1992). Most structures use polysilicon as the mechanical material, but other films, including polymers and metals, have also been employed. The availability of reactive ion-etching processes to define patterned features precisely in the deposited thin films has also been an important factor in the progress achieved.

In spite of its many desirable features, surface micromachining is limited to the fabrication of structures with vertical features of the order of few microns because of the intrinsic limitations of thin-film deposition methods. When micromechanical devices require structures of tens of microns or more, alternative technologies such as wafer bonding or dissolved-wafer processes must be employed. For instance, microstructures as thick as 20 μm have been fabricated by Suzuki (1990) by using a bulk dissolved-wafer process in conjunction with reactive ion etching. Microstructures with much higher thickness-to-width ratio can be fabricated with x-ray lithography and electroforming (LIGA) processes (Munchmeyer and Langen, 1992).

Originally developed in Germany, where the acronym "LIGA" was coined (from *litographische galvanoformung*), this method uses x-ray synchrotron radiation lithography to produce extremely precise polymer molds of three-dimensional microstructures on a supportive substrate to generate them subsequently by electroplating metal films. The main attraction of this technology is the large thickness-to-width tolerance (up to 300:1) that results from the short photon wavelength and the thickness of photosensitive polymers. No other technique allows the fabrication of truly 3D microstructures that have the ability to generate large forces and torques.

All these microstructures should be efficiently integrated at the system level. A number of important efforts are presently under way to establish interface standards for next-generation smart microelectromechanical devices that can operate with a VLSI interface chip to implement local intelligence, self-testing, and autocalibration capabilities, as well as bus compatibility at the system level.

Although significant progress has been made in some classes of microstructures (most notably, microsensors), an immense number of challenging problems remain to be answered before microsystems technology can really take off. Greater understanding, characterization, and control of the mechanical properties of thin films, such as stress and strain, is badly needed. The removal of stress by new annealing techniques will have to be achieved in order to design, simulate, and fabricate new and more complex microsystems that can perform as predicted. Improved connectivity, packaging, and assembly techniques will need to be developed. All these issues must be the focus of great attention ahead. Solving these problems will demand years of interdisciplinary effort from leaders in engineering, physics, chemistry, biology, and business in universities as well as industrial laboratories.

3. MICROELECTRONIC MECHANICAL DEVICES: MICROMETER MACHINES

In this section, we discuss machines in the size range between 1 and 10^{-3} mm. To describe these machines accurately, we call them microelectronic mechanical devices. Here, we focus on two types of microelectronic mechanical devices that are playing an increasingly important role in the development of this field: *microactuators,* which convert electrical signals into mechanical motion, and *micromechanical sensors,* which convert mechanical motion into electrical signals. We discuss the principles, the most common structures, and the fabrication processes for these typical microelectronic mechanical devices, illustrating state-of-the-art technologies with the first version of commercial products.

Three important factors have motivated a high level of interest in microelectronical mechanical devices. They are summarized as follows:

1. High efficiency: If we consider a machine of feature size L, we find that the mass of the movable part is proportional to L^3. Here we assume that the velocity of the movable part is proportional to L. Although there is no direct link between the feature size and the velocity, it gives a reasonable relation in the size dependence of velocities, which is effective in the dimension analysis. Under this assumption, the momentum is proportional to L^4, and the kinetic energy $\frac{1}{2}mv^2$ is proportional to L^5. This means that the momentum and the kinetic energy can be reduced by the order of 10^{-4} and 10^{-5}, respectively, by reducing the size. In other words, conversion from electricity to motion in actuators can be achieved with extremely small energy compared with larger machines. By the same argument, the efficiency of motion to electricity conversion in sensors can also be extremely high.
2. Low cost and high reliability: In terms of practical feasibility, massive production is possible with batch fabrication processes similar to those employed in the industrial production of VLSI chips. This naturally leads to significant cost reduction. Indeed, fabrication processes with precise quality-control methods translate into high-quality and cost-effective manufacturing alternatives with high reliability.
3. Integration with electronic circuits: The basic fabrication process for the microelectronic mechanical devices is fully compatible with silicon integrated-circuit technology. This permits the monolithic integration of electromechanical devices and electronic microcircuits in the same piece of silicon, enabling a high degree of device functionality, such as self-test and self-calibration, which could not be achieved otherwise. It should be noted that in the two examples described in this section, namely a digital micromirror device and a microaccelerometer device, the micromechanical elements are monolithically integrated with silicon CMOS circuits that electronically control the function of the micromechanical devices. This "smart actuator/sensor" approach is essential to achieve a systems design with high functionality and massive parallelism of the microelectronical mechanical devices.

The above factors have significantly contributed to accelerating the pace of the research and development effort in this field. Commercial production of microelectronic mechanical devices has entered its initial stages, and a variety of novel devices have started to appear in the market (Cho *et al.*, 1989).

3.1 Microactuators

Many research groups have been trying to exploit various types of forces in the design of microactuators: electrostatic (Fan *et al.*, 1988; Mehregany *et al.*, 1990; Kikuya *et al.*, 1993), magnetic (Yanagisawa *et al.*, 1991), piezoelectric, and the force derived from shape-memory alloy, to name a few. All these forces usually originate from electricity. Thus, microelectronic mechanical devices effectively cover most microactuators.

Among the various types of microactuators using the above forces, those employing electrostatic forces have been the devices most extensively studied. They provide good examples of successful electricity-to-motion conversion. In the following subsections, we describe two different types of microactuators that use the electrostatic force: micromotors and digital micromirror devices.

3.1.1 Micromotors The demonstration of the side-drive micromotor developed by Fan *et al.* (1988) at the University of California, Berkeley, caused public sensation, triggering substantial research activity in microelectronic mechanical devices. Figure 2 shows the top view and the cross section of the stepping motor they developed. The biasing and the phasing schemes are shown here. The motor consists of a rotor and a stator, both made of 1.0- to 1.5-μm-thick polycrystalline silicon thin film. The rotor rotates around a hub, which is also made of polycrystalline silicon thin film. The diameter of the rotor is 120 μm and the gap between the rotor and stator is 2 μm. When pulse voltages of around 100 V are applied to the stator poles from the peripheral circuits with different phases ϕ_1, ϕ_2, ϕ_3, a torque of the order of piconewton meters arises due to the electrostatic force between the rotor and the stator, which are offset, as shown in Fig. 2. A synchronous motor was also developed by the same researchers, achieving an experimental speed of 500 rpm.

Shortly after the Berkeley micromotor demonstration, Mehregany *et al.* (1990) at the Massachusetts Institute of Technology fabricated and demonstrated a side-drive micromotor with a 100-μm diameter that rotates at the much higher speed of 15 000 rpm with a continuous operation lifetime of about a week. By carefully analyzing the motion of the micromotor, these researchers developed a structure that significantly reduced the friction between the rotor and the stator, which were fabricated with heavily phosphorus-doped polysilicon thin films. They also demonstrated that 7000 micromotors can be built on a 4-in. (10-cm) silicon wafer in a batch process compatible with CMOS VLSI fabrication. Figure 3 shows the different fabrication steps for this micromotor (Mehregany *et al.*, 1992). The fabrication process employs the sacrificial oxide technique and uses polycrystalline-silicon thin-film technology. First, the initial sacrificial layer is deposited and patterned. Then, the bushing mold is etched, as shown in Fig. 3(a). Next, a 2.5-μm-thick phosphorus-doped polysilicon film is deposited and patterned, as illustrated by Fig. 3(b). The second sacrificial layer is

then deposited and a 1-μm-thick polysilicon thin film is deposited, and patterned, as shown in Fig. 3(c). The bearing is patterned, according to Fig. 3(d). Finally, the first and second sacrificial layers are removed by HF etching to complete the structure shown in Fig. 3(e). Figure 4 shows a scanning electron micrograph of the micromotor.

Micromotors have not found practical applications yet. The friction between the rotor and the axle still needs to be reduced significantly in order to guarantee a practical lifetime. However, the broad impact of micromotor laboratory demonstrations has activated wide interest in the world of micromachines, accelerating significantly the investigations of electronic mechanical devices.

3.1.2 Digital Micromirror Devices The digital micromirror device (DMD) is one of the few microactuators that has found a clear practical application: the use in large-screen projection displays (Hornbeck, 1993; Younce, 1993).

The DMD is a micromechanical, reflective spatial light modulator consisting of an array of rotatable aluminum mirrors, monolithically fabricated over a conventional CMOS SRAM address circuit. It was invented in 1987 by Hornbeck (1989) at Texas Instruments. Figure 5 shows the schematic cross

section and the latest structure of the DMD (Hornbeck, 1993). The aluminum mirror is suspended over an air gap by two thin, mechanically compliant torsion hinges supported by posts that are electrically connected to an underlying bias/reset bus. The address electrodes and the landing electrodes are on the same plane as the hinge. There are two air gaps: one between the mirror and the underlying hinges and a second one between the address electrodes and the underlying third metal level of the CMOS SRAM structure. The structure is fabricated by the sacrificial layer technique in which organic material is etched away. Because the hinges are hidden from the surface, they cannot diffract light. Therefore, they do not degrade the contrast ratio. Each aluminum mirror rotates independently +10° or −10° by an electrostatic force between the address electrode and the aluminum mirror. Although the DMD can be operated in an analog mode, the mirrors are biased in such a way that only the digital landing states of +10° or −10° are possible. The response speed is 10 μs, which is fast enough to use the device digitally in the full-color projection display system. By addressing the SRAM, any pattern of +10° or −10° rotated pixels can be arranged in the two-dimensional micromirror array.

A full-color projection display using one DMD is possible using an optical system that includes a light source, a color filter wheel, condenser lenses, and a zoom projection lens, as shown in Fig. 6 (Hornbeck, 1993). The pixel structure has been improved to achieve high contrast ratio and high optical efficiency. A 768 × 576 hidden-hinge DMD has been tested, and system contrast rations up to 100:1 have been measured. Very high optical efficiency (>60%) is obtained on account of high reflectivity of the aluminum mirror (>90%) and the high ratio of the mirror area (>75%) in the pixel. In durability tests at Texas Instruments, the DMD has

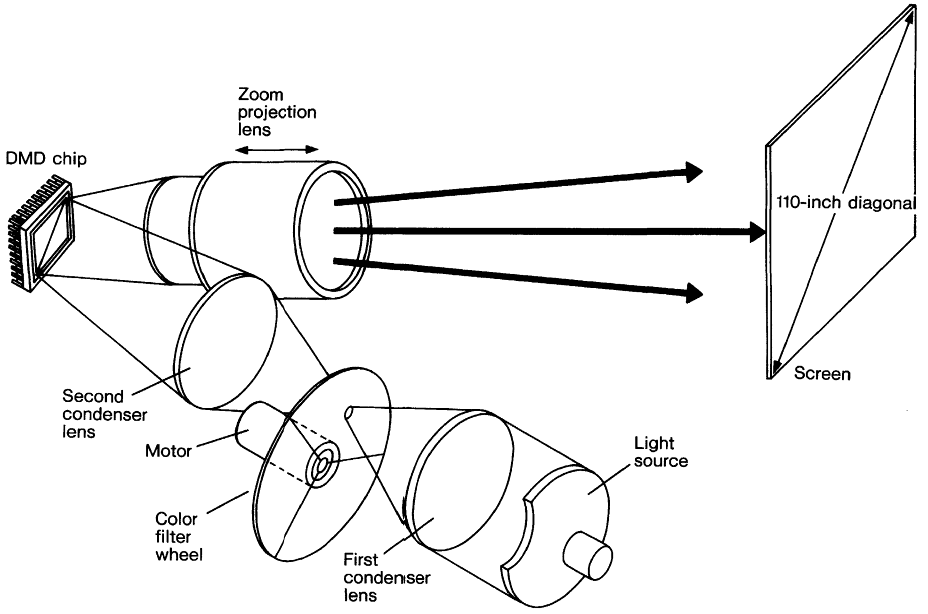

FIG. 6. Full-color projection display using the DMD (Hornbeck, 1993).

shown no fatigue failure after several hundred billion cycles (the equivalent of about four years of continuous operation), proving the ruggedness of this electronic mechanical device.

3.2 Microsensors

Micromechanical sensors convert mechanical motion to electrical signals (see MICROSENSORS). Among a variety of smart sensors presently being studied, the integrated microaccelerometer has found recent applications in the automobile industry, where it is now employed as a key component of airbag safety systems.

Figure 7 summarizes the schematic structure and the function of an integrated microaccelerometer developed at Analog Devices (Goodenough, 1991; Core *et al.,* 1993). The device consists of a micromechanical sensor monolithically integrated with a CMOS electronic circuit on the same silicon substrate. The sensor has fixed capacitor plates and a moving capacitor plate, both made of doped polycrystalline silicon thin film. The moving capacitor plate is formed by the sacrificial etching technique. Special efforts were made to reduce the residual stress in the polycrystalline silicon thin films (Core *et al.,* 1993). When the sensing part is accelerated, the moving part moves and the capacitance between the fixed plates and the moving plate changes. This change in capacitance is detected and electrically processed by the CMOS circuits. A linear output is obtained in the (0–50)g range.

3.3 Intelligent-Microsystem Technologies

As we have seen in the previous examples, the first generation of commercial products using microelectronic mechanical devices is beginning to emerge and state-of-the-art technologies are being developed to mass produce several other intelligent microdevices in the near future. Novel applications may be found in optical-communication hardware systems, in which precise alignment with accuracies of the order of 1 μm is required (see OPTICAL INTERCONNECTIONS). Kikuya *et al.* (1993) have successfully demonstrated an optical-fiber alignment mechanism using electrostatic forces to align optical fibers to optical devices such as lasers or photodiodes. This technology could be applied to the alignment of one- or two-dimensional optical-fiber arrays in various mas-

sively parallel optical interconnection schemes (Shirai *et al.*, 1993). Driven by the strong market demand for advanced optical-communication systems, further applications of smart microelectronic mechanical devices may increase rapidly.

Traditionally, most microelectronic technologies such as thin-film deposition, patterning, and photolithography have been used in the fabrication of micromechanical structures, either directly or with minor modifications. As VLSI technologies evolve to smaller and smaller ULSI size dimensions, micromechanical technologies will continue to catch up with these ever-higher levels of integration. It is thought that micromechanical technologies will fully merge with VLSI technologies, allowing new sophisticated functionalities that result only from the technology fusion. From what we are presently seeing, it is reasonable to expect that various technologies from different fields will merge into truly intelligent-microsystems technologies, creating totally new capabilities for future sensors and actuators. Furthermore, these advanced microelectronic mechanical devices will give birth to intelligent micromachines, which should eventually be an integral part of the next-generation communications networks that will act as interface between human beings and their environment.

4. NANOELECTRONIC MECHANICAL DEVICES: NANOMETER MACHINES

We define "nanomachines" as ultrasmall structures whose feature size is smaller than one micron (1 μm = 10^{-6} m) but greater than one nanometer (1 nm = 10^{-9} m), a range that corresponds to the so-called "mesoscopic" realm. Nanoscale fabrication is expected to play a central role in the next technological frontier after the enormously successful development of microelectronics. Thus, nanotechnologies are likely to affect many research areas, such as precision engineering, automated manufacturing, environmental sciences, and medicine, in a very profound way. Although we have already seen the experimental fabrication of nanoscale devices in many laboratories, nanotechnologies are still only in an embryonic stage. Therefore, it is quite unclear what form nanomachines will take as nanotechnologies mature in the years to come, possibly well into the twenty-first century (Ball and Garwin, 1992). Figure 8 compares several possible fabrication processes that are presently being ex-

plored as alternative approaches to assemble nanostructures: conventional microelectronics, biochemistry, and other novel methods.

Recent developments in microelectronics have already allowed the fabrication of mesoscopic devices. Ultrasmall structures, such as quantum wells, quantum wires, and quantum dots, in which electrons are confined to potential wells in two, one, or zero dimensions, are leading to new electrical and optical properties (see ELECTRON STATES IN ZERO-, ONE-, AND TWO-DIMENSIONAL STRUCTURES; HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR). By using advanced epitaxial deposition techniques, one can readily make artificially quantized structures. By means of atomic steps or terraces on highly pure single-crystal surfaces, it is possible to make very small (diameter < 100 Å) wires (see MOLECULAR-BEAM EPITAXY). Thus, electrons can be confined and controlled or released in this dimension. At present, however, this atomic-scale manipulation is usually restricted to one dimension. On the device surface plane, the minimum feature size is limited by the lithographic resolution. Thus, microelectronic fabrication methods have a resolution limit of about 100 nm due to the photon wavelength used in x-ray lithographic patterning. Using electron-beam lithography, the patterning resolution can be extended down to 20 nm, a limit enforced by the physical properties of the polymers employed as resist masks in this process. Therefore, further feature size reduction and greater design flexibility in the fabrication of nanoscale structures and device systems will require a radical departure from the conventional microelectronic technologies so successfully being used today. In this section, we describe three promising new approaches that might lead to the development of such nanotechnologies: optical manipulation of small particles, molecular self-assembly or chemical synthesis, and near-field scanning probing.

4.1 Optical Manipulation

Optical manipulation uses photon pressure to trap and assemble small-size particles, and ultraviolet light to link them together by adhesion. Optical pressure arises from changes in photon momentum. When we assume light power P of 1 mW (a typical laser light power), the magnitude P/c, where c is the speed of light, is about 3×10^{-12} N. This force is nearly equal to the force of gravity on a sphere whose radius is 4.3 μm and its density is 1 g/cm^3. Therefore, we can use a laser beam to levitate small particles. For particles whose diameter is larger than the laser wavelength, the principle of optical trapping is explained as follows (Ashkin, 1980). Let a sphere with refractive index higher than that of the surrounding medium be placed off-axis at position Q in a Gaussian beam, as shown in Fig. 9(a). Rays a and b refract through the sphere, giving rise to forces F_a and F_b in the direction of the momentum change. Since there is more light at a than at b, $F_a > F_b$. This results in a (transverse) gradient force F_{tr} and an axial force F_{ax}. The gradient force pulls the sphere into the high-intensity region and traps it at the laser focus. Optical trapping by the axial force is also possible in air with a single, vertically directed laser beam, as shown in Fig. 9(b). For particles whose diameter is smaller than the laser wavelength, the trapping force is calculated by electromagnetic theory (Wright, 1993; in this calculation, the microsphere was assumed to be polystyrene in water). The maximum axial force decreases proportional to r^3 for a radius less than 0.1 μm.

The use of optical tweezers, a useful extension of the phenomenon of optical trapping, was first demonstrated by Ashkin *et al.* (1986). The optical manipulation of individual small particles is achieved by noncontact and nondestructive methods using the equipment shown in Fig. 10. A Gaussian-mode Nd:YAG laser, with a wavelength of 1.06 μm, is used for micro-object trapping and rotation. The beam is strongly focused by a microscope objective lens (NCF Plan 100x, N.A. = 1.25) onto the micro-object. The laser power on the micro-object surface is varied from 1 to 100 mW for the experiment. The trapping behavior is recorded with a CCD camera.

Optical tweezers have found diverse applications in fields such as biotechnology (Berns *et al.*, 1992) and microchemistry (Kuo and Sheetz, 1993), where they have been used to demonstrate cell fusion and to measure mechanical properties of intracellular components (Block *et al.*, 1989) as well as to perform microchemical spectroscopic analyses, among other uses. State-of-the-art optical systems presently allow the manipulation of particles whose diameter is greater than 20 nm and smaller than 50 μm.

In order to build three-dimensional nanostructures, a multibeam laser scanning manipulation system was developed and used to demonstrate the simultaneous trapping and

adhesion of multiple particles (Misawa *et al.*, 1992). Any well-defined polystyrene structure can be assembled with this system by sequentially repeating these optical manipulation and photopolymerization procedures.

A fabrication process uses physical motion to shape, move, and assemble different components into a predesigned system. If we could use optical pressure to rotate shaped elements of the mesoscopic world, we could drive such components and eventually assemble them together, manufacturing nanomachines.

As an initial step in such direction, dissymetric micro-objects fabricated by reactive ion-beam etching (RIBE) have been rotated in water by optical pressure (Higurashi *et al.*, 1994). When a dissymetric micro-object is trapped, it stands perpendicular to the substrate and parallel to the optical beam axis. In this position, it begins to rotate around the optical axis in the desired direction. Figure 11(a) shows a schematic view of the optically induced rotation of a microfabricated SiO_2 object. The rotational mechanism is described as follows. The anisotropic shape and scale of the designed micro-object are shown in Fig. 11(b). The optical pressure is based on the photon momentum change shown in Fig. 11(c). The ray refraction on the object side surfaces (i) and (ii) produces a momentum change. Thus, radiation pressure is conveyed to the object, which gives rise to a torque, as illustrated by Fig. 11(d). A microscope photograph of the trapped micro-object is shown in Fig. 11(e).

As was discussed in Sec. 3.1.1, electrostatic micromotors usually have a short lifetime on account of the surface friction between the rotor and the axle body. Since optically induced rotation requires no mechanical or electrical contacts, we believe it will play a significant role in novel photomicrodynamical systems (Ukita *et al.*, 1993). Furthermore, future research should pave the way for the optical drive technique to be applied to nanoscale mesoscopic objects with the long-term goal of making the fabrication of nanomachines possible.

4.2 Molecular Self-Assembly

Molecular self-assembly uses weak and nondirectional bonds, such as ionic bonds, hydrogen bonds, and van der Waals interactions, to obtain a final structure that is a thermodynamically minimum state. Examples of nanostructures based on self-assembly are shown in Fig. 12. The oligomer in Fig. 12(a) has an interesting helical structure based on the coordination of bipyridyl units to copper ions (Whitesides *et al.*, 1991). The toroidal *bis*-bipyridinium cyclophane in Fig. 12(b) is able to move back and forth along the backbone, a fact that has suggested its existence in the fanciful "molecular abacus" (Whitesides *et al.*, 1991). The molecular necklace in Fig. 12(c) is fabricated from

complexes of poly (ethylene glycol) bisamine with α-cyclodextrins by capping the complexes with 2,4-dinitroafluor-benzene. Polyethylene glycol penetrates the "breaker-like tunnel" of the α-cylodextrins (Harada *et al.*, 1992).

The use of reversible, noncovalent interactions to assemble molecules into aggregates of nanometer size will most likely be eventually successful. Tachibana *et al.* (1992) demonstrated an example where molecular self-assembly can be controlled. In the future, we should be able to assemble artificial nanoelectronic mechanical devices that are stronger and lighter than any microelectronic mechanical devices available with present-day manufacturing processes (Ball and Garwin, 1992).

4.3 Near-Field Scanning Probes

Condensed-matter physics has supported the extraordinary progress in electronics, and physicists are now extending their wide knowledge of bulk solids to the physics of surfaces, which become increasingly more important as device dimensions shrink. The invention of near-field scanning probes (SPM), such as the scanning tunneling microscope (STM) by Binnig and Rohrer in 1982 (Binnig *et al.*, 1982) and the atomic force microscope (AFM) four years later (Binnig *et al.*, 1986), has dramatically advanced our understanding of the physics of surfaces (see TUNNELING MICROSCOPY).

The near-field scanning probes use the near-field interaction between a sharp probe and the sample of interest for atomic-level surface modification (Leung and Goh, 1992). These techniques are able to handle individual atoms and molecules with extraordinary control and precision (Betzig and Trautman, 1992). For instance, surface scanning mechanisms for the STM have been developed, as shown in Fig. 13. A small probe is placed on a single-head beam. During experimental observation, the precision mechanism is scanned in the x,y direction, while the motion in the z direction is servo-controlled to hold a chosen electrical quantity constant (e.g., the tunneling current from the tip of the probe to the surface of a conducting sample). The head detects the probe's movement to observe the surface morphologies.

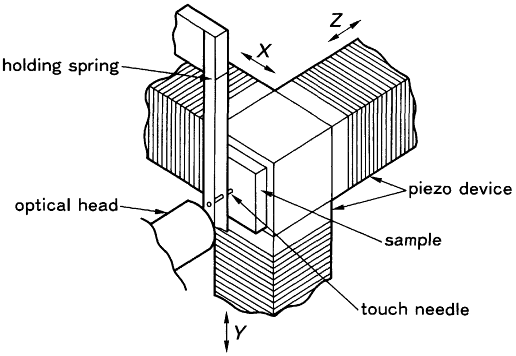

FIG. 13. Surface scanning precision mechanism for STM.

Using xenon atoms, IBM scientists drew the letters of "IBM" (Eigler and Schweizer, 1990), and researchers at NTT drew a cartoon of Albert Einstein (Utsugi, 1990) using similar STM techniques (see Plate 1). These remarkable achievements were in fact the world's first atomic-level designs. The force used to remove atoms from surfaces is the origin of friction and wear, and SPM has become a powerful tool for exploring these forces (Mate *et al.*, 1987). On the other hand, robust computer simulations of molecular dynamics that can be used to trace the movement of each atom between contacting or sliding surfaces have been developed (Landmann *et al.*, 1990). The synergy between advanced experimental techniques and powerful computer analysis has allowed the recent study of atomic-level microtribology on well-defined solid surfaces (see TRIBOLOGY). It is still quite difficult to apply these studies to "real world" surfaces, which are usually not well defined, contaminated, and not homogeneous. However, untangling these complicated mechanisms will no doubt play an important role not only in achieving no-wear micromechanical conditions but also allowing atomic-level structure modification and nanometer machining.

5. SUMMARY AND CONCLUSIONS

The miniaturization of machines has long been an important goal of technology development in many fields. In fact, it was over three decades ago that Richard Feynman delivered the now famous speech "There's Plenty of Room at the Bottom" (Feynman, reprinted 1992). His view of developments to come was remarkable in many ways. Feynman anticipated the sacrificial-layer method of making silicon micromotors, the use of electrostatic actuators, and the importance of friction and lubrication in such devices. The speech, presented in 1960 to an audience of scientists and engineers at the Jet Propulsion Laboratory (JPL), addressed the problem of manipulating and controlling things on a small scale. The question Feynman posed in the opening remarks of his lecture (Why cannot we write the entire 24 volumes of the *Encyclopedia Britannica* on the head of a pin?) startled his audience by revealing the staggering small world that still remained beneath the miniaturization levels of those early days. With remarkable vision, the leading late physicist accurately predicted the coming age of information storage on an atomic level. Although we are still not quite there, present-day developments give a clear indication that artificial precision machines on such level will indeed one day exist. In fact, Feynman himself had the opportunity to discuss his early predictions in the light of many late developments when he gave a lecture on "Infinitesimal Machines" (Feynman, reprinted 1993) 23 years later to a similar audience at the same place, as a sequel to his earlier speech.

Many important scientific and technological achievements have helped advancing the road toward the realization of Feynman's ultimate dreams in a dramatic way. As we have discussed in the present article, this recent decade has brought many impressive developments in micromachine technology. However, at the current technology level, there are still a number of serious problems to overcome. Many important sensors are yet to be fully miniaturized. There is no straightforward way of using the force delivered by actuators. Energy sources are not compact and efficient enough. There are few suitable microsystems for processors. Communication tools between different subsystems are primitive, if existant. It is difficult to build truly three-dimensional structures with complex functional parts. With all these tough hurdles to face, practical applications of intelligent-microsystems technologies are not likely to become widespread in the near future. Indeed, despite significant progress, flexible artificial systems where fully self-sufficient micromachines can dynamically adapt to changing environments are still a long way from being realized. Nevertheless, despite the difficult challenges ahead, there seems to be little doubt that such technological scenarios will happen one day. The uncertainty is when. No one questions the direction in which technology is moving, but there are major discrepancies about the time frame it will take to reach such ambitious goals.

GLOSSARY

Accelerometer: A device that detects changes of acceleration.

Actuator: A device that creates mechanical motion from other forms of energy.

DMD (Digital Micromirror Device): A micromechanical two-dimensional array of rotatable aluminum mirrors, monolithically fabricated over address-integrated circuits.

Electrostatic Micromotor: A motor, monolithically fabricated using surface micromachining, that rotates as a result of electrostatic forces.

LIGA Process: A technique developed in Germany that uses x-ray synchrotron radiation lithography to produce extremely precise polymer molds of three-dimensional micromechanical structures on a supportive substrate to generate them subsequently by electroplating metal films. The acronym used derives from the German words for lithographic (*lithographische*) electroforming (*galvanoformung*).

Lithography: A method to delineate patterns by means of selectively exposing a resist material that is sensitive to irradiation by light, x-ray, or electron beams.

Micromachine: Small functional structure whose feature size is smaller than 1 mm but greater than 1 μm (1 $\mu\text{m} = 10^{-6}$ m).

Nanomachine: Ultrasmall functional structure whose feature size is smaller than 1 μm but greater than 1 nm (1 $\text{nm} = 10^{-9}$ m).

Near-Field Scanning Probes (SPM): Atomic-scale microscopy technique that uses the near-field interaction between a sharp probe and a sample for atomic-level surface modification, such as scanning tunneling microscopy (STM) and atomic-force microscopy (AFM).

Optical Interconnection: A connection between two nodes using optical paths.

Optoelectronics: The combination of optics and electronics.

Sacrificial Etching: A technique used to fabricate micromechanical structures by depositing a thin film on top of a sacrificial layer that is then removed by etching (typically chemical).

Sensor: A device that transforms a physical or chemical perturbation into an electrical signal.

Surface Micromachining: Micromechanical structure fabrication on the surface of a substrate.

Ultrasonic Micromotor: A motor monolithically fabricated using surface micromachining that uses, as driving force, the high-energy ultrasonic vibration caused by the mechanical distortion of piezoelectric material.

Wafer Bonding: A technique to stack and bond two substrates (typically silicon) by facing the clean surfaces and then annealing them. This technique, widely used to fabricate SOI (silicon on insulator) electronic devices, can also be used to build micromechanical structures.

20.1
Introduction

To investigate the interaction between matter and matter there are, in principle, two complementary experimental setups known. In a collider, two nuclei accelerated in opposite directions, are brought to collision at a given point and the products of the reaction are detected. Alternatively, a beam of particles is accelerated onto a fixed target, and the reaction products are similarly detected; this is the subject of this chapter. The fixed target setup, as is depicted schematically in Figure 20.1, gives the possibility of combining any two elements of the periodic table.

This chapter is meant to give an overview of the different targets applied in particle accelerators and also to serve as a short introduction to the material demands and the techniques established for their production. It is not meant to be treated as a textbook, but rather as a guide for people new to this field, so we have provided an extensive bibliography furnishing details of the original publications.

The chapter is an update of the famous review by Heagney, Heagney and Maier (1997). The scientists who dedicate their work or at least a part of it in producing and developing targets are members of the International Target Development Society (INTS) (*www.intds.com*).

Sections 20.2–20.5 of this chapter are dedicated to the description of solid targets ordered by their production processes. Section 20.6 deals with strategies to increase their lifetime. Internal targets, applied in storage rings, which can be solid, cryogenically cooled, or gaseous, are discussed in Section 20.7. Section 20.8 describes liquid targets, that are mainly applied for higher beam intensities. High-precision measurements often require highly enriched isotopes as target material, which often implies special production processes, this topic is discussed in Section 20.9. The chapter concludes with a section on characterization of targets and a brief outlook of future developments in this field.

20.2
Thin-Film Targets

In this section, deposition techniques that are relevant for thin-film target production are described briefly and the necessary or optional accessories like backings, parting agents, and protective layers are explained.

Thin films are produced by different deposition techniques under vacuum. The methods differ generally in the way the

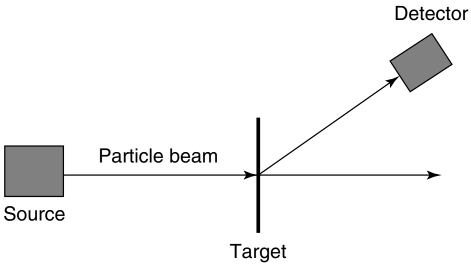

Fig. 20.1 Schematic view of a fixed target setup.

starting material is heated. If it is available as a solid piece or a solid rod, or if an inert crucible material for the process is available, thermal evaporation can be applied.

For high-melting substances or for those for which no crucible is available, either heating by an electron-beam gun or deposition by sputtering is suitable.

For a comprehensive review of this vast topic, please refer also to Muggleton (1987). Grossmann, Maier, and Friebel (1997) give an overview of the production of radioactive thin-film targets in the Munich hot-lab facility and describe specially designed resistive-heated microsources for evaporation as well as crucibles heated indirectly by electron bombardment. With these techniques, they reach a very high efficiency, which is crucial for the often scarce actinide target materials they work with and the high activities involved.

The yield differs widely for the different techniques discussed and additionally depends strongly on the applied geometry. The technique has to be chosen according to the necessary active target area and the required homogeneity of the target layer, taking into account the price and availability of the target material. Then the process has to be optimized in respect of material consumption, yield, and homogeneity of the layer.

An option to increase the thickness homogeneity and the yield of target material is to rotate the substrate or several substrates, respectively, above the evaporation source during the process; see Figure 20.2.

There is a group of targets that are specific not from the aspect of material or from the technique of deposition, but from the way they are mounted. For some experiments, for example, lifetime measurements of isomers with the recoil-distance method, it is essential to have a target surface as flat as possible to get a defined distance between the target foil and a detector. For these so-called plunger targets, the target layer has to be stretched over cone-shaped target frames, as is described, for example, by Grossmann, Maier, and Friebel (2006); alternatively, even two foils can be stretched parallel to each other in a fixed distance for a differential measurement (Zell and Dewald, 1989).

20.2.1
Thermal Evaporation

Some substances are available as massive pieces or rods to be clamped into electrodes and to be heated directly by resistance heating, as is described for carbon in Section 20.2.3. For all other materials, a crucible has to be found that does not react with the starting substance until the evaporation temperature is reached. Typical crucibles are either made of metals with a high melting point, for example, Mo,

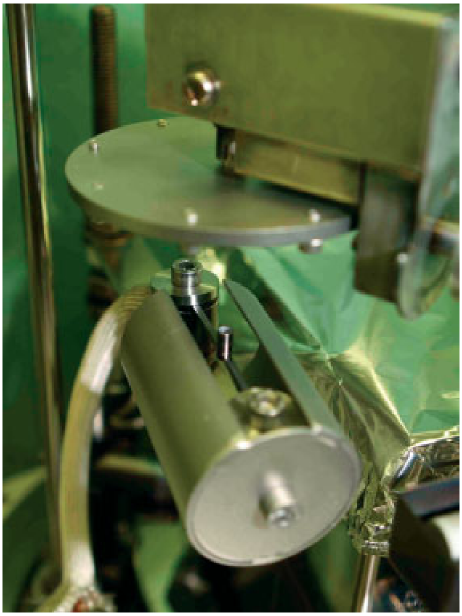

Fig. 20.2 Thermal evaporator: Tantalum crucible underneath a rotating substrate holder.

Pt, Ta, and W, or of carbon, or of ceramic compounds like BN or Al_2O_3.

At 10^{-6} or 10^{-5} mbar the material in the crucible is heated until it evaporates significantly, which happens at a vapor pressure of about 10^{-4} mbar. The vapor condenses as a thin film on the cold substrate. The difference between melting temperature and the temperature at which the material evaporates significantly defines the ease with which the process is controlled. Under high vacuum conditions, the mean free path of vapor atoms is of the same order as the vacuum chamber dimensions, so these particles travel in straight lines from the evaporation source toward the substrate. In thermal evaporation techniques, the average energy of vapor atoms reaching the substrate surface is generally low, which is advantageous for the removal of thin films from a substrate to obtain a self-supporting film.

Good candidates for thermal evaporation either out of a tungsten or of a tantalum crucible are, for example, Ag, Al, Au, Bi, Cu, Ga, Ge, Fe, In, Ti, Pb, Sn, and Zn. Though the amount of material needed for thin self-supporting targets (and the dimensions) are typically small, for highly toxic materials such as Be, Cd, or Th, the safety precautions are very important: see, for example, (Stoner, 1997; Grossmann, Maier, and Friebel, 2004) for the production of beryllium foils up to a thickness of 1 μm.

The evaporation of very volatile materials poses an additional difficulty, since they tend to stick preferably at the colder parts of evaporation chamber rather than on the substrate. They can be forced to condense on the required substrate either by high vapor stream density or by a low substrate temperature. Maier *et al.* describes this explicitly for Zn and Cd Maier *et al.* (1989) and Szerypo for HgS (Szerypo *et al.*, 2008).

While for natural materials the deposition process has to be optimized to reach a good homogeneity to obtain the required thickness, to reduce impurities from the crucible or substrate, and to get intact, pinhole-free foils, the deposition for isotopically enriched material poses an additional problem that has to be solved. Because of the limited availability of, and the often enormous prices for, highly enriched material, the process has to be optimized with regard to homogeneity and material consumption. With thermal evaporation, a yield of about 50% for a target homogeneity of ±5%, a target thickness significantly below 1 μm, and target dimensions of about 20 cm^2 can be reached. Good examples are targets of several erbium and lead isotopes, as described by Folger *et al.* (1999).

For several targets, a compound is applied instead of the pure material. This is done for two different reasons: For the rare earth materials and the low radioactive actinides, uranium and thorium, the fluoride has a much lower melting point and can be easily evaporated thermally (Thomas and Greene, 1995). The opposite is the reason for applying, for example, PbS instead of lead or Bi_2O_3 instead of the metal. The higher melting point of the compound leads to better performance and a longer lifetime of the target in the beam (Kindler *et al.*, 2006). Hg is liquid at room temperature, so HgS is one of the feasible compounds that may be used as a solid target (Szerypo *et al.*, 2008). This is discussed in detail in Section 20.6.

For materials with a very low melting point or materials that are typically available as compounds, the preferable process can be reductive evaporation. The reduction process and the choice of reductant is described in detail in Section 20.9. Reductive evaporation results in the deposition of the reduced material on a backing or a substrate in this process; see (Maier *et al.*, 1989; Maier and Grossmann, 1987; Lommel *et al.*, 2006) for Pb, Zn, Cd, and Sm.

20.2.2
Electron-Beam Evaporation

In electron-beam evaporation, the coating material rests in a water-cooled copper hearth so that it stays cold at the contact surface and a reaction or alloying of the target material with any hot crucible surface is prevented. An electron beam is generated in a heated filament, electrostatically accelerated, and – depending of the type of gun – deflected on the surface of the target material. The electron beam can either be focused to a point or can be wobbled across a larger area of the surface of the material.

Electron-beam evaporation is the ideal means for the production of targets out of refractory metals like W or Ta. The material consumption in this method, at least with commercially available standard electron guns, is rather high. This is a drawback when isotopically enriched targets are needed. To overcome this problem, there have been modifications to commercial guns, as described by Thomas *et al.* (1991) or even the development of a very compact electron gun that is optimized for the production of targets for accelerators by Heagney and Heagney (1985, 2004).

The method is applied preferably where refractories like tungsten are used as target material (Folger *et al.*, 1997; Stoner and Jolivet, 2006) but also for example, in magnetic layers of Gd (Maier-Komor *et al.*, 2004) and large area targets of ^{28}Si prepared by electron-beam evaporation (Greene and Berg, 2005).

20.2.3
Carbon Targets and Carbon Stripper Foils

Carbon is a very special material related to applications in accelerators not only as target and stripper foil but also as a backing for other materials, as is discussed in detail in Section 20.2.5. Though stripper foils are not really targets, they play a central role in cyclotrons, linacs, and tandem accelerators, and they are almost exclusively made of carbon. They are mostly developed and prepared by the same community, making use of almost the same techniques as targets, which justifies this issue also being addressed within the scope of this section.

Because of this broad range of applications of carbon foils, a number of investigations and developments are dedicated to the production of carbon with a special focus on high durability and long lifetime upon irradiation of the foils. Some preparation techniques are almost exclusively discussed in connection with carbon foils. These techniques are summarized in the following section. For a review of the different techniques for preparation of carbon foils, see also Stoner and Miller (2006) and the comprehensive citations therein.

20.2.3.1 **Resistance Heating**

In this method, spectroscopically pure carbon is heated directly by a high current in a high-vacuum recipient. There are, in principle, two different ways of arranging the carbon. Lommel *et al.* (2002) clamp a spectroscopically pure carbon rod vertically between water-cooled electrodes. Since in this arrangement the sublimation of the carbon upon resistive heating takes place over a zone of several centimeters of the rod, the method allows a deposition of large areas and a wide thickness range from some micrograms per square centimeter up to about $100\,\mu\mathrm{g\,cm^{-2}}$. Muggleton (1987), for example, applies two pointed carbon rods of high purity clamped in water-cooled electrodes that are held in contact while a current of approximately 200 A passes through them. The carbon sublimes preferably at the junction of the two rods. This method is mainly used for the production of thin carbon layers of up to $5\,\mu\mathrm{g\,cm^{-2}}$.

20.2.3.2 **Carbon Arc Evaporation**

Carbon arc evaporation is one of the earliest processes for producing carbon foils and strippers and has been investigated and improved over the decades. In this technique, two ultrapure carbon rods are mounted in a vacuum recipient. With one electrode fixed and the other one movable, a carbon arc is ignited and the carbon atoms are evaporated with significantly higher energy compared to conduction heating, resulting in quite differently structured carbon layers. As described, for example, by Takeuchi *et al.* (1979) different electrode designs and either an alternate current (ac) or a direct current (dc) are applied.

Sugai *et al.* (2006) developed stripper foils that consist of alternating layers of carbon prepared with ac and dc arc-discharge technique, respectively. Carbon foils from a dc arc discharge show a good durability against high-intensity beams, but are rather fragile, whereas foils ablated from both electrodes in an ac arc discharge have a comparably short lifetime in a high-intensity beam, but are mechanically very strong. Doping the carbon electrodes with different elements leads to an increase in the thickness achievable.

Jaggi *et al.* (2006) report on the production of carbon foils that have a thickness of $100–200\,\mu\mathrm{g\,cm^{-2}}$ with carbon arc deposition, which show an enhanced lifetime in high-power cyclotron applications.

20.2.3.3 **Deposition by Electrical Discharge or Pyrolysis**

Auble *et al.* (1980) produced carbon foils of thickness $2–10\,\mu\mathrm{g\,cm^{-2}}$ by vapor deposition and by cracking of a gas mixture of 10% argon and 90% ethylene in a dc glow discharge.

Liechtenstein *et al.* (1997, 1999) used glow discharge sputtering deposition with a low-density krypton plasma to produce thin diamond-like carbon foils (DLC foils) as stripper for tandem accelerators and compared the durability with those produced with other methods.

20.2.3.4 Laser Ablation

In pulsed laser deposition (PLD) or pulsed laser ablation, the source material is irradiated with a high-intensity laser beam of more than 100 MW cm^{-2} and instantaneously evaporated. The evaporated material is ionized and accelerated by the laser beam, and it condenses on a suitable substrate. An advantage of PLD compared to other deposition techniques is the possibility of controlling the amount deposited on the substrate by the number of laser pulses, but to guarantee the reproducibility of deposition it is mandatory to move the target perpendicular to the laser beam after each pulse to avoid burning of holes. Other advantages are that (i) the stoichiometry of the target is transferred exactly to the substrate, (ii) multilayers are produced easily, and (iii) the process is suited for computer control. Furthermore, it is possible to simultaneously prepare layers of different material classes like metals, semiconductors, ceramics, or polymers.

The disadvantages are that (i) the deposition rates are rather low and (ii) the formation of unwanted droplets is possible. The method is only suitable for small areas and the equipment is relatively expensive; the laser beam entrance window, especially, is problematic when the thickness of the required layer becomes too high.

Dollinger and Maier-Komor (1991) adapted the laser ablation technique for producing durable carbon stripper foils for application in tandem accelerators in an ultrahigh vacuum plant with a Nd:YAG laser. They later upgraded their set up with a vacuum interlock, thus increasing the obtainable foil thickness that had earlier been limited by the decreasing transmission of the laser beam entrance window. For details, please refer to (Maier-Komor, Dollinger, and Krücken, 2006) and citations therein.

20.2.4
Sputtering Techniques

It is very difficult, or almost impossible, to prepare some materials as thin targets with evaporation techniques such as, for example, high-melting elements like refractory metals when isotopically enriched material is needed, or for compounds that easily decompose upon heating.

It is common to all sputtering methods that the deposition of the target atoms does not depend on the vapor pressure since sputtering is a purely ballistic process that is relatively cold in the sense that substrate heating during deposition is negligible. This implies that the substrate can be placed relatively close to the source resulting in a high efficiency of the processes and also that heat-sensitive materials like plastics can be applied as substrates or backings.

Sputtering techniques are also advantageous for materials with a low ''sticking coefficient'', such as cadmium, which are extremely difficult to condensate on substrates with thermal methods. In general, sputtering methods lead to excellent condensation and good adhesion to the substrate. On the other hand, this can be a problem when self-supported layers are needed.

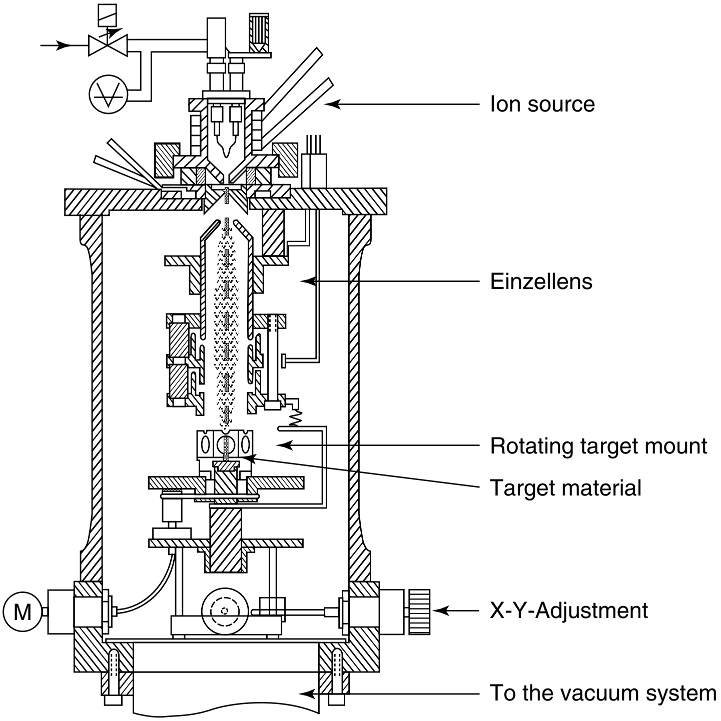

Fig. 20.3 Sketch of a Sletten-type focused ion-beam apparatus.

20.2.4.1 Focused Ion-Beam Sputtering

Heavy or focused ion beam sputtering was one of the first sputtering methods applied for the production of targets for accelerators in the case of scarce materials.

As shown in Figure 20.3, an argon ion beam is extracted from a duoplasmatron ion source into a high-vacuum chamber and focused to a beam spot of diameter smaller than 2 mm. The ions are accelerated to about 10 keV onto the cathode. The material to be deposited is placed on the cathode in the form of a bead or pressed powder inside the beam stop around which the substrates are arranged concentrically. Details of the process are described by Sletten and Knudsen (1972), who developed the technique especially for isotopic targets of refractories and oxides. Some further applications can be found, for example, in Folger, Klemm, and Müller (1983) and Kindler *et al.* (2004).

The major advantage of the focused ion-beam sputtering is the small beam focus possible and the extreme efficiency of the method that makes it possible to work with very small amounts of starting material. For this reason, focused ion-beam sputtering is particularly suitable in all cases where the target material is scarce or expensive.

On the other hand, the close geometry of the setup leads to a reasonable uniformity of the deposited layers only for small target areas and the small beam focus results in low deposition rates and in extremely long deposition times for thick or large layers. Another drawback of the technique is the rather complex and bulky electrical supply, which makes it expensive and complicated.

20.2.4.2 Saddlefield Ion-Source Sputtering

Instead of a duoplasmatron source, Drinkwater (1982) describes the application of a saddlefield ion source for the production of the above-mentioned problematic materials. A saddlefield ion source, as is described, for example, by Muggleton (1991) or in a modified version by Turkentine and Weisser (1997), is mounted in a vacuum chamber and the ion beam is focused on the surface of the sputtering target with 30° inclination.

Maier (1991) discuss the application of high-vacuum sputter deposition for the production of various nuclear accelerator targets. Here, a beam of xenon atoms or ions produced by a saddlefield-type source is applied. Targets of a wide range of different materials are made and characterized and the foils are reported to be of high purity and excellent mechanical strength (Greene *et al*. 1997). The method is applied not only to metals but also to oxides that are sputtered from the compound with an additional O_2 partial pressure and to nitrides that are sputtered reactively from metal targets with a nitrogen partial pressure present in the deposition chamber.

Sputtering with a saddlefield ion source can also be used for etching or thinning of foils down to 0.5 μm or even thinner, as is described by Thomas and Greene (1993, 2003).

Since this technique combines the advantages of a small beam focus and a high efficiency of the focused ion-beam sputtering with a rather compact and easy-to-operate setup that works reliably with respect to long-term runs, it has become a powerful and commonly used technique for the production of difficult small-size thin-film accelerator targets in many laboratories.

20.2.4.3 Magnetron Sputtering

In magnetron sputtering, ions, most commonly of argon or other noble gases, are produced in a low-pressure glow discharge. The ions are then concentrated by the magnetic field of a permanent magnet situated below the sputtering target and are accelerated on to the surface of the sputtering target by an electric field.

Conducting materials can be sputtered with a dc source whereas for insulators an RF magnetron is needed. The equipment is rather expensive and the material consumption high, especially since the starting material has to be available in the form of a sheet of at least 1 in. diameter. The method is advantageous for refractory materials and in all cases where a good adhesion to a substrate is required. Also large-area targets can be produced with a good homogeneity (Kindler *et al.*, 2004). The method also provides the opportunity to produce mixed targets by cosputtering different kind of materials from different sources in parallel or to do a reactive sputtering by using a suitable sputter-gas mixture.

Magnetron sputtering of magnetic materials like iron, cobalt, or nickel is very problematic since the magnetic susceptibility of the sputtering target interferes with the field of the permanent magnets of the magnetron source and the ignition of the plasma is impossible. Weidong *et al.* (2002) use an assisting magnetic field produced by a stack of permanent magnet rings above the sputtering target for the preparation of Fe targets with a thickness of up to 1000 nm. Kindler *et al.* (2004), on the other hand, use a stack of thin foils of Co or Ni each not thicker than 250–300 μm, to produce targets with a thickness of 100 $\mu g\,cm^{-2}$ for Co and 200 $\mu g\,cm^{-2}$ for Ni.

Sometimes, the availability of the wanted target material in the form of a suitable sputtering target can be problematic, especially in the case of ceramic materials, which are mostly pressed and/or sintered. The homogeneity and density of commercially available sputtering targets is difficult. For isotopically enriched materials, the only possibility for magnetron sputtering is to apply a rolled foil. But this is only an option for isotopes that are not too expensive.

20.2.5
Backings

For several materials, there is no substrate and no parting agent available to produce a self-supporting target or the desired target layer is too thin to make it self supporting. In these cases, a backing is needed, which supports the layer, does not affect the target material, and does not interfere too much with the intended measurement. The backing thickness should be homogeneous, and the surface should be clean and free from imperfections, as a deposition typically duplicates the quality of the substrate. The starting material should have a high purity and should not diffuse into the target material.

In many cases, carbon is an ideal backing, as it can be produced with high purity, made self-supporting over a wide thickness range, and prepared very thin, down to $5\,\mu g\,cm^{-2}$. Additionally, it has a very low Z, which allows, when dealing with significantly heavier reaction products, an easy separation of the relevant signals from the target material from those signals coming from nuclear reactions of the beam with the backing. But if the production process or the application is thermally or mechanically very stressful for the target-backing combination, a metal is preferable. With respect to a metal backing with a low Z, beryllium is often the material of first choice. However, for beryllium one must be able to ensure that no beryllium oxide is produced during the production process or in the application, as beryllium oxide is highly toxic. Alternatively, aluminum or titanium can be applied as a backing.

There is a large variety of plastic foils available, which have the same advantage of measurement as explained for carbon backings above. The disadvantages for plastics are their modest thickness homogeneity, no defined composition, a low heat resistivity, and a poor electrical conductivity, which can cause problems in their production as well as during the experiment. Polyethylene, polycarbonate, polyvinyl, polyimide are the plastics usually applied. The thinnest commercially available plastic is Mylar, a polyethylene terephthalate, which can be bought with a thickness down to $2\,\mu m$. Kapton, a polyimide, which is mechanically and thermally fairly stable, is commercially available down to $7\,\mu m$, but has been produced down to $44\,\mu g\,cm^{-2}$ ($\sim 0.5\,\mu m$) by Pauwels *et al.* (1979) or down to $10\,\mu g\,cm^{-2}$ ($\sim 0.07\,\mu m$) by Stolarz and van Gestel (2006).

For applications that do not observe the transmitted products, all good-quality thin films that are available can be feasible backings.

For in-beam γ-ray experiments, the backing has to be thick enough to stop the beam or the recoil, but it should not contribute to the expected γ-spectrum. In this case, the backing material and the backing thickness are determined by the expected energy range of the signals.

20.2.6
Protective Layers

To hinder sputtering in the beam or to reduce the oxidation of a sensitive target material, protective layers are applied.

Carbon and gold are commonly used as protective layers, depending on whether a very low Z or a fairly high Z is required, as they can be easily separated from the reaction products to be measured. Both materials are easily available and can be deposited by several techniques. Both materials are stable under air, even under moist conditions, and have a fairly high sublimation or melting point, respectively.

Depending on the experiment, all other materials feasible for evaporation can be applied. The deposition process for the protective layer should not heat the target too much or damage it. The material of the protective layer should preferably not interfere with the experiment or diffuse into the target material, which might be a problem with gold depending on the target material. In addition, the deposition should be feasible over a large thickness range.

In the beginning, for target production for heavy-ion accelerators, targets dipped in organic lacquer or paint were commonly used. As these organic substances often are neither suitable for ultrahigh vacuum conditions nor for an intense beam, this is no longer an option.

20.2.7
Parting Agents and Substrates for Self-Supporting Targets

As targets are typically needed to study the interaction of a projectile with the target, a defined material of a defined purity and a defined thickness is needed.

The ideal target is elemental and self-supporting. This is the main difference from the production process of commercially produced thin films. Even if most of the techniques are related, the demand for a self-supporting thin film makes the difference. A major task in the target production is preparing the substrate in such a way that the target layer can be removed and a complete intact film without any additional impurities is obtained.

In principle, two different techniques are applied: either there is a substrate available on which the desired target can be deposited as a film and which can be dissolved completely after the process, or a flat glass or metal substrate is coated with a soluble intermediate layer on which the target is subsequently evaporated.

The substrate or substrate plus intermediate layer has to be strainless, smooth, and homogeneous with as little structural unevenness as possible, since any structure of the substrate is reproduced by the deposited layer. It should be chemically stable and no trace of the material of the substrate should be finally found in the target.

In the early stages of heavy-ion targetry, depositions on collodion, which gives a celluloid-like film, were used for quasi-self-supporting target production. As the collodion film is not stable in a heavy-ion beam, the beam burns off the substrate during the experiment. Recent measurements in atomic physics show that the leftover collodion corresponds to a substrate thickness of 2–5 $\mu g\,cm^{-2}$ with an uneven thickness distribution, which cannot be tolerated by all experiments. So nowadays, collodion should be considered more like one of the feasible plastic backings (see Section 20.2.5). The papers by Braski and by Gao *et al.* (2007) give a good comparison between the target surface roughness obtained by applying a

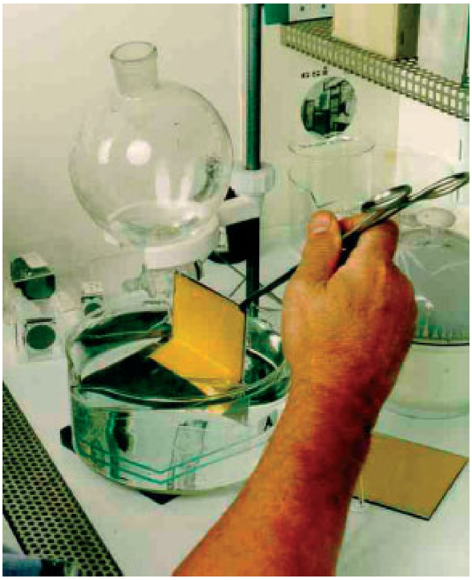

Fig. 20.4 Gold foil fetched with a frame.

crystallized intermediate layer and by using plastic backings.

For the alternative substrate plus soluble intermediate layer, a whole variety of water soluble intermediate layers mainly deposited on glass substrates exists. Evaporated alkali halides, for example, NaCl, CsI, or $BaCl_2$, tensides (detergents), or betaine–sucrose are frequently applied. The process of floating is shown for a gold foil in Figure 20.4. Scientists from all countries typically apply well-known branded detergents. The alkali halides and betaine–sucrose have the major advantage of being much more stable at higher temperatures, but the application process has to guarantee that the intermediate layer crystallizes in an acceptable smoothness as the structure is repeated by the deposited layer, and this should not lead to unbearable roughness. However, a little roughness allows the foil to release tension during drying and upon irradiation. For the alkali halides, it is an optimization between substrate, preferably glass, evaporation velocity, and distance. They are evaporated thermally on slides or very smooth glass; a comparison of the roughness achievable is given by Braski (1972). For betaine–sucrose, the production process, the mix ratio, and the humidity during the coating play a major role (Lommel *et al.*, 2002; Maier-Komor, 1972; Thalheimer *et al.*, 1999).

For the other possibility of depositing directly on a soluble substrate, copper is very often the material of choice. The copper foil should be fairly clean, 99.9% or better, flat, without any structure from recrystallization or cold rolling, strainless, preferably thermally stress relieved. The requirements are given by the need to release a complete, strainless, pinhole-free, and clean target. For the copper substrate, nitric acid is a typical solvent, depending on the deposited target material. The concentration of the acid is chosen to allow a slow solution process (Folger *et al.*, 1997; Kirchner *et al.*, 1981; Meens, Rossini, and Sens, 1993).

In principle, for a self-supporting target, any material for which there is a known solvent that will dissolve the substrate material without dissolving the target material is feasible as a substrate

20.3
Rolled Targets

Metal targets in the thickness range of micrometers are preferably prepared by rolling a thick foil in a sandwich of clean stainless steel plates in a mechanical rolling mill, with successive rolling giving thinner foils. Depending on the material, often, even on the charge available, foils down to several hundreds of micrograms per square centimeter can be achieved (Karasek, 1963; 1972; Folger, 1999).

For very ductile metals like indium or lead, the application of a pack of teflon sheets either instead of, or inside, the stainless-steel pack is advantageous to prevent the soft material from sticking to the inside surface of the pack, as described by Clifford *et al.* (2002).

Rolling metals sensitive to oxygen or moisture, for example, calcium, sodium, or uranium, down to a thickness of a micrometer or even thinner, is a difficult task (Maier, 1982). Good results are obtained by rolling in a glove box in an inert-gas atmosphere with an oxygen- and water-content below 1 ppm.

Some metals with a very low rollability at room temperature have to be prepared at higher temperatures. Therefore, the material is packed between stainless-steel plates, heated up to temperatures at which the ductility is higher, and then immediately rolled in the hot pack. This process has to be repeated until the desired thickness is achieved. After about 50% of thickness reduction, a heat treatment under vacuum for stress relief is necessary. It is important to keep the temperature below the recrystallization temperature. For beryllium, tungsten, and vanadium, this process is discussed in detail by Karasek (1979). The area achievable for a foil depends on the width of the rolls. Parameters that can be varied are the velocity of the rolls and the amount of blocking up of the rolls after each run, which determines the pressure exerted on the foil. Another way to influence the quality of the foil is to either roll it always along the same axis or to rotate the pack after each cycle through 90° or 180°, respectively.

Commercially available hot rollers can be heated up to 150 °C with hot liquid running through the rollers, thus keeping them at a constant temperature, which is suitable for several plastic foils such as polyethylene or polypropylene.

The process parameters for cold rolling metals out of isotopically enriched material can differ significantly from those obtained for natural ones, since the ductility of metals depends crucially on the impurities of the starting material. As the production process for isotopic material differs from the production process of commercially available high purity metal, the ductility and the behavior when rolling might differ. Cleaning processes in advance may be necessary (Manente and Blunt, 1995; Maier, 1989).

20.4
Preparation of Targets by Electrochemical Deposition

Electrochemical deposition (ED) techniques are widely used in cases where the desired target material is available only in limited amounts, is highly radioactive, or both. The advantages of these methods are their simplicity and deposition yields approaching 100% in select cases as well as the capability of producing a wide range in target thicknesses from a few micrograms per square centimeter up to several milligrams per square centimeter. Since for ED, a compound of the target material is dissolved in either aqueous or organic solvents, easy and complete recovery of precious target material is possible in case the deposition is incomplete. In principle, one can distinguish three different techniques:

1. Electroplating, where a thin metallic film is deposited onto a substrate that serves as the cathode in the deposition cell;
2. Electrodeposition of insoluble hydroxide compounds of highly electropositive elements, which cannot be deposited in metallic form from aqueous solutions; and
3. molecular plating, where deposition is performed from organic solutions such as isopropyl alcohol or acetone.

20.4.1
Electroplating

Here, the material of interest is deposited from ionic solutions by means of electrolysis. At the cathode, the dissolved ions are reduced to the elemental state and a metallic film of the desired element results (Paunovic and Schlesinger, 2006). Since electroplating is also widely used for industrial coatings on different substrates, a large number of procedures for the deposition of elements such as Cr, Ni, Zn, Ag, and Au are available and can be adapted for target fabrication. Target thicknesses of several milligrams per square centimeter are possible. The method is suitable for isotopic enriched material owing to high efficiency of up to 90%. Metallic foils or carbon might be used as substrates. Self-supporting targets can be produced by removing the substrate after completion of the deposition process by means of selected etching solutions. In this way, self-supporting Os targets with an average target thickness of 500 $\mu g\,cm^{-2}$ have been produced using Cu as substrate for electroplating and subsequent removal of the Cu backing by dissolving the Cu in a mixture containing trichloracetic acid and ammonia (Cecchi, 1991).

20.4.2
Electrodeposition

Metallic films of highly electropositive elements such as the lanthanides or the actinides cannot be produced by electroplating. In these cases, deposition of the hydroxide can be performed from aqueous acidic solutions containing NH_4Cl or NH_4NO_3 as electrolyte. At current densities up to several amperes per square centimeter, hydrogen is evolved at the cathode and the desired elements are deposited in the form of their hydroxides by the hydroxyl ions that are generated at the cathode (Hansen, 1959; Evans *et al.*, 1972; van der Eijk, Oldenhof and Zehner, 1973; Trautmann and Folger, 1989; Da Cruz and Poldena, 1990; Becerril-Vilchis *et al.*, 1996; Ingelbrecht *et al.*, 1997; Bajo and Eikenberg, 1999; Eberhardt *et al.*, 2001). For electrodeposition, the backing (the cathode) must be inert in highly acidic solutions and thus, metal foils of Ti, Ta, or Pt are most often used. Small target spots with a diameter of about 3 mm can be prepared.

20.4.3
Molecular Plating

For molecular plating, the lanthanide or actinide compound, typically the chloride or the nitrate, is dissolved in a small

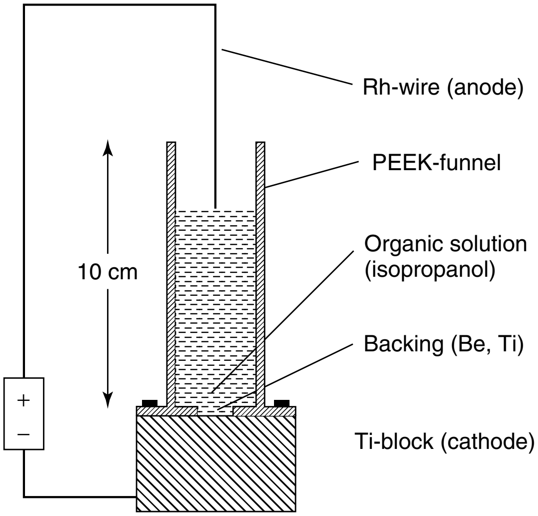

Fig. 20.5 Schematic view of the cell used for molecular plating (Eberhardt *et al.*, 2004). A funnel made of polyether-etherketone (PEEK) confines the area to be plated and acts as a solution container with a volume of 15 ml. The backing foil is sealed to the funnel by means of a Viton O-ring and a Ti block that serves as the cathode. An Rh wire is used as anode material.

volume (5–10 μl) of nitric acid and the aqueous phase is mixed with a surplus of an organic solvent (a few milliliters). The suitable solvents are isopropanol, isobutanol, or acetone. Under these conditions, no electrolytic dissociation occurs by applying an electric current at voltages up to 3000 V (Eberhardt *et al.*, 2001; Parker and Falk, 1962; Parker, Bildstein, and Getoff, 1964; Parker *et al.*, 1964; Getoff and Bildstein, 1965; Filippone and Wahlgren, 1986; Eberhardt *et al.*, 2004). It is assumed that the dissolved molecules form clusters that migrate in the electric field toward the cathode. However, the deposition process is not yet completely understood. In general, the composition of the deposition is complex and also contains possibly fragments of the solvent molecules. In cases where Be or Al is required as backing material, molecular plating must be applied, since these materials quickly dissolve in acidic solutions and thus electrodeposition is not possible. Figure 20.5 shows a schematic view of a cell used for molecular plating. The same setup can also be applied for electrodeposition.

20.5
Bulk Targets

There are applications where targets with a thickness of millimeters or even centimeters are needed. Some examples are production targets for pions or for exotic nuclei in fragment separators or parts related directly to the ion optics of the accelerator such as the energy degrader. In these cases, often elaborate mechanical preparation of shapes and surfaces is necessary. The samples have to be cut, turned, polished, and lathed, sometimes with high-precision requirements. Surface quality and accuracy of the target thickness over the whole relevant beam-spot area is especially a crucial point since the interaction that a particle beam experiences in a target and the energy loss of the particle beam in a degrader both depend directly on the amount of matter the beam passes. Therefore a lateral inhomogeneity in the thickness of the target or degrader inadvertently leads to a broadening of the reaction peak or a spreading of the momentum distribution of the beam particles. A good example for a complex variety of targets out

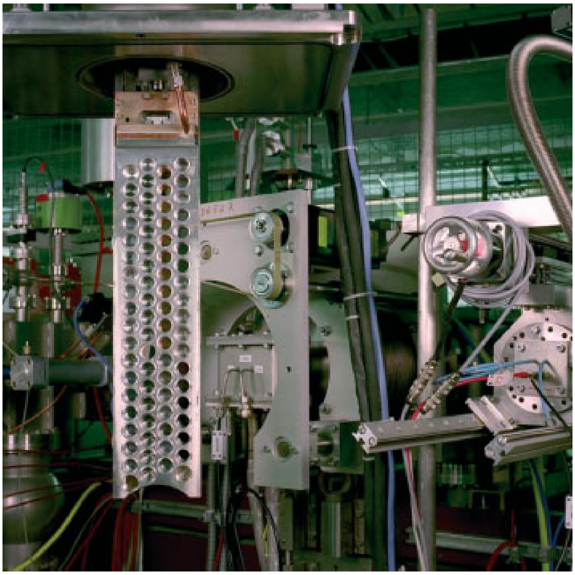

Fig. 20.6 Target ladder at the fragment separator FRS at GSI.

of different materials with different surface conditions and different thicknesses is the target ladder shown in Figure 20.6 in which 74 production targets for the fragment separator at GSI are mounted (Folger *et al.*, 1991).

Sometimes, the starting material is only available as a powder, for example, for some compounds like oxides or fluorides. In these cases, the pressing of tablets can be a rather straightforward method to get usable targets. For this purpose, a hydrostatic press with appropriate dies is typically used. Sometimes, simultaneously heating or evacuating the die is advantageous. Pressing a tablet of the starting material can also be a necessary preparation for applying the material in a thermal or electron beam-gun evaporation process.

Stolarz (1997) describes powder sedimentation from a glue solution as a very effective technique for preparing rather thick targets (25–65 $\mathrm{mg\,cm^{-2}}$) from enriched isotopic materials such as ruthenium-96 with high melting points and a hardness that makes pressing of pills inapplicable.

Sugai (1997, 1999) developed a target preparation method in which a powder is deposited by high-energy vibrational motion of particles in the electrostatic field between parallel electrodes, the so-called HiViP-method. The target material in form of a powder is placed in a cell consisting of two parallel metal discs serving as electrodes and separated by a pyrex tube. On the inner side of the two electrodes, a metallic backing foil of aluminum or copper is clamped. By increasing to high voltage slowly, the powder particles become charged, and at a particular voltage a vibrational motion of the particles sets in. The deposition takes place at about 10 kV over a period of 5 to 15 hours at room temperature and at ambient pressure. Data for various target materials and different thicknesses are given. The foils do not show a shiny metallic surface but are slick black. However, they are of high mechanical strength combined with a good homogeneity and high purity.

Using this method, free-standing targets of 50–125 mg cm^{-2} of natural silicon as well as enriched ones of Si-28 have been also prepared successfully; this is rather difficult with any other method (Sugai *et al.*, 2006).

20.6
Strategies for Increasing the Target Lifetime

While dealing with solid-state targets, there are cases where the intensity of the particle beam impinging on the target is too high for the target material. Evaporation or partial melting of the target layer leaving droplets on the backing or holes in the layer are the consequences, as described, for example, by Lommel *et al.* (2002). Different possibilities for the enhancement of target lifetime are discussed in this section.

One measure to prevent overheating of the target is to rotate it through the beam thus distributing the beam intensity over a larger target area and, at the same time, giving each target time for cooling before the next beam pulse hits. This method probably was mentioned for the first time by Organessian *et al.* (1975) at the Joint Institute for Nuclear Research in Dubna, Russia. To date, it has been applied and improved upon over there (Lobanov *et al.*, 1997) and at GSI in Darmstadt, Germany (Münzenberg *et al.*, 1989; Schädel, 2006) especially for experiments in nuclear physics and chemistry. The concept is adopted in a number of facilities worldwide, for example, the Argonne National Laboratory in Argonne, USA (Greene, Thomas, and Leonard, 1995; Roa *et al.*, 1996; Greene *et al.*, 2004) and at Grand Accelerateur National d Ions Lourds in Caen, France (Stodel *et al.*, 2006). Yoshida *et al.* (2004) at RIKEN, Japan also use the rotating-wheel concept and combine it with an additional cooling for two very different target types. In one case, they apply a massive rotating disc out of carbon, for example, which is in contact with a water-cooled plate, thus further increasing the tolerable beam intensity. In the other case, they operate a wheel with thin targets that rotates in a He-atmosphere providing a convective cooling. Antalic *et al.* (2004) describe measurements for various fixed targets and rotating target wheels in vacuum as well as in a stationary He-gas and a He-gas flow as cooling media.

For the highest intensities – where the energy deposition is too high for solid materials to survive – the use of liquid metals as targets is also under development, as is described in Section 20.8.

A totally different approach to enhance the durability and the lifetime of targets for some special cases is the substitution of the elemental material for a compound. For experiments in superheavy element synthesis, where high beam intensity is essential because of very low reaction cross sections, targets of lead and bismuth are frequently used. To overcome the problem arising from the very low melting temperatures of these metals, different higher melting compounds were investigated for the SHIP-experiment at GSI (Lommel *et al.*, 2002) and thereupon lead was substituted for PbS and bismuth was substituted for Bi_2O_3 (Kindler *et al.*, 2006). Similar problems emerge with materials that have a very high vapor pressure or are even liquid in the elemental form. Maier-Komor (1985) report on suitable compounds for phosphorus, sulfur, mercury, and iodine targets. Greene and Lister (2002) test different compounds for the application of sulfur targets and Szerypo *et al.* (2008) describe the preparation of HgS as an alternative. An application of compounds can also be necessary when the desired element is chemically unstable, such as some of the rare earth, alkaline, or alkaline earth metals that oxidize rather fast when exposed to air. In these cases, often the halides or the oxides can be used; see, for example, (Maier-Komor, 1989).

20.7
Internal Targets

For high-precision experiments, storage-ring operation with internal targets – in combination with phase-space cooling – is often an attractive alternative to single-pass experiments. Since the beam is passing an internal target typically with a frequency of 1 MHz, the target has to be several orders of magnitude thinner than necessary for a single-pass experiment.

Therefore internal targets installed in storage rings in combination with electron-cooling of stored ion beams are a well-established technique to perform high-precision experiments (Melissinos and Olsen, 1975; Stringfellow *et al.*, 1986; Ekström, 1992; Macri, 1984). The large number and variety of internal target types that have been developed and are in operation worldwide is the result of various technical and scientific boundary conditions (Baglin *et al.*, 1980; Kilian *et al.*, 1982; Burgei *et al.*, 1982; Pollock, Miller, and Singh, 1980; Popov, 1990). The design and the technical realization of each internal target has to optimize the conditions for the physics experiments to be made. Maximum luminosity (target thickness (atoms per square centimeter) times particle-beam intensity (particles passing through the target per second)) has to be reached under optimized duty-cycle conditions of the storage ring (particle-beam lifetime, accumulation time, and cooling time). Schematically, the large number of existing internal targets can be divided into two main types: gas targets and solid targets; additionally, cryogenically cooled liquid beams, which are a sort of intermediate type of internal targets, are also addressed.

20.7.1
Gas Targets

Gas targets are realized by the expansion of a gas through a nozzle into the vacuum system of the target installation. As storage rings are mainly operated under ultra-high vacuum (UHV) conditions ($p < 10^{-10}$ mbar), the effect of the gas load created by the gas inlet on the storage-ring system has to be minimized. Technical solutions are multistaged differential pumping and skimming sectors inside the installation (Dick and Kubischta, 1986; Gruber *et al.*, 1989; Reich *et al.*, 1997). Gas target density (target thickness) strongly depends on gas species, nozzle geometry, inlet pressure, and inlet temperature (Hagena and Obert, 1972; Krämer *et al.*, 2001). Adjusting these parameters, reachable target densities vary between 10^{10} atoms cm^{-2} (pure gaseous) and approximately 10^{15} atoms cm^{-2} (gas cluster). This flexibility in target species and target thickness makes gas targets a universal installation mainly chosen at existing storage rings. The existing gas target setups were usually designed to be used in a specific experimental setup (atomic physics and nuclear physics), optimized to deliver a well-defined target thickness of a specific gas species, but can be used with other gases species with decreased performance. A special type of construction are gas targets delivering polarized gas atoms created by an atomic beam source in combination with a storage cell (Steffens, 1991; Steffens, 1990; Mairon *et al.*, 1991).

20.7.2
Solid Targets

Solid targets in storage-ring environments are realized with the use of different materials in different forms (Ekström, 1992; Macri, 1984). Thin fibers or microribbons can be introduced into the circulating particle beam (Koch *et al.*, 1988; Lozowski and Hudson, 1991). Microparticles (e.g., dust) may be enclosed in a cell or injected as a beam, or pellets (frozen drops) are created in a generator and move across the particle beam (Bickel *et al.*, 1990; Tanabe, Sugai, and Yasue, 1987; Meyer *et al.*, 1990; Trostell and Kullander, 1990). As solid targets locally have a target thickness of approximately 10^{19} atoms cm^{-2}, problems could occur in particle-beam cooling performance and also in the storage-ring duty cycle.

The use of internal targets has been discussed at several conferences, workshops, and accelerator schools where detailed information is given in the form of reports (Ekström, 1992; Macri, 1984; Kilian *et al.*, 1982; Krämer *et al.*, 2001; Steffens, 1991; 1990; Holt, 1984; Oelert, 1987).

20.7.3
Cryogenically Cooled Liquid Targets

For many experiments, like those planned at the future Facility for Antiproton and Ion Research (FAIR) at Darmstadt, low-Z internal targets, that is, hydrogen and helium, are particularly important. Laval-type nozzles with a diameter of $d_0 = 100\,\mu\text{m}$ or greater are typically employed, providing a target density in the interaction region in the range $n{\sim}10^{11}-10^{14}\text{cm}^{-3}$ and a target spatial extension that spreads out over several millimeters. These features (low density and large interaction length) make gas-jet internal targets unsuitable for several storage-ring experiments that require a luminosity in the order of 10^{30} or greater. Larger target densities and smaller interaction lengths can be achieved by further cooling the gas to temperatures down into the liquid regime, below 20 K for hydrogen and below 4 K for helium.

Producing liquid beams of helium and hydrogen, however, is not straightforward. To make these beams entirely compatible with the high-vacuum conditions in a storage ring, the use of sub-10-micrometer diameter nozzles is mandatory. On the other hand, nozzle-clogging represents an experimental challenge when micrometer-size apertures are used. Thus, microscale liquid jet operation requires scrupulous cleaning at all stages of beam preparation, submicrometer filtering of the liquid, and the use of gases with ultrahigh-purity. These experimental issues have been extensively investigated recently and the feasibility of producing liquid beams from $d_0 = 2$-μm-orifice diameters has been demonstrated by Grisenti (2003) for both helium and hydrogen Grisenti *et al.* (2006).

20.8
Liquid Targets

Liquid targets are used sometimes when the target material needed actually is a liquid or a liquefied gas; in such cases the material is handled mostly in cells as for gases (see Section 20.7.1).

Additionally, in recent years, liquid targets have been discussed intensely in connection with high power applications at accelerators where the energy deposited in the target is too high for standard solid materials to withstand. Other concepts to withstand higher energy depositions are described in Section 20.6.

Liquid metals have been in use as coolants for more than 30 years in nuclear reactors worldwide; lithium, sodium, and lead–bismuth alloys have been in use and the techniques for handling and pumping them are well established. Other applications of liquid metals include cooling of detectors; in 1977, Grand and Goland even proposed a closed loop of liquid lithium as a windowless target for a high-power neutron generator in a material test facility for future fusion reactors (Grand and Goland, 1977). For an overview of the applications in the past as a basis for the new developments, see Nolen *et al.* (2002) and the citations therein.

In connection with high energy deposition in targets, there are basically two different fields of application where intense development for liquid targets is in progress. One is the production of radioactive isotopes for nuclear reaction experiments that had, in the past, only been possible with stable isotopes. The other field is the operation of high-intensity proton accelerators for the generation of intense neutron beams in spallation sources or for the production of neutrinos and muons for particle-physics research. In all applications, the liquid metals act as target and coolant simultaneously.

For the production of radioactive isotopes again there are, in principle, two different approaches: the in-flight method and the isotope separation online technique (ISOL), which were planned to be combined in the rare isotope accelerator (RIA). With the in-flight technique, exotic nuclei are produced by fragmentation and fission of heavy projectiles on low Z target materials. For high power fragmentation targets, Nolen *et al.* (2003) propose a windowless jet target of liquid lithium operated in a close loop suitable for intensities in the 400-kW range for a uranium beam. Such a target was planned for RIA and also for its follow-up version ''RIA-lite'' (Nolen, 2007); it is proposed as a possible solution for the fast extraction mode of the planned Super-FRS (Fragment Separator) of Gesellschaft für Schwerionenforschung GSI (Geissel *et al.*, 1977). For the new high acceptance fragment separator of the National Superconducting Cyclotron Laboratory (NSCL) at Michigan State University (MSU) – the A1900 – a hybrid target is being constructed as high power production target for lighter beams where thicker target layers are required. To reduce the target thickness, liquid lithium flows through a channel in a tapered beryllium block connected to a rigid stainless-steel loop thus acting as coolant and at the same time as target material (Nolen *et al.*, 2003b; Morrissey *et al.*, 2003).

In the ISOL technique, usually a proton or light-ion beam is directed onto a thick target to produce the rare isotope at rest and then a postaccelerator is employed to provide a secondary beam. For high power facilities of this type, Nolen *et al.*, (2002) proposed a two-step target where a porous tungsten block acting as primary neutron converter is cooled with liquid lithium and is surrounded by a secondary target of fissionable material. This concept involves some hazards with liquid lithium being in direct neighborhood of water-cooled and fissionable material. Bollen *et al.* (2006) describe, alternatively, a concept based on liquid mercury as primary target, which has the advantage of being not flammable.

Neutron spallation sources traditionally work with refractory metal targets. For new or upgraded facilities that will work with intense beams in the megawatt-regime, liquid metal targets are being studied or are under construction and material behavior and corrosion in high-intensity, high-radiation environments are being investigated (Mansur, 2006). The Swiss Spallation Neutron Source (SINQ) at the Paul Scherrer Institute (PSI), the most powerful accelerator-driven facility worldwide, is running a pilot experiment for a megawatt liquid metal spallation target (MEGAPIE) in a joint international initiative. It is planned to work with liquid lead–bismuth eutectic in a closed loop and will be operated at around 200 °C (Bauer, Salvatore, and Heusener, 2001). Amongst others, a closed loop of liquid mercury in a container as a spallation target is under construction for the Spallation Neutron Source (SNS) at Oak Ridge National Lab (ORNL) (Mansur and Haines, 2006) and in the Material Life Science Facility (MLF) of the new Japan Proton Accelerator Research Complex (J-PARC) (Oyama, 2006) as well as projected for the European Spallation Source (ESS) (Bauer and Ullmaier, 2003).

Nishimura (2002) propose a liquid metal target station without a window where liquid bismuth is pumped in the upward direction through a tube, spilling over the rim and then returning to the reservoir tank. The charged particle beam comes from above, thus hitting the free surface of the liquid metal.

Ravn *et al.* (2003b) also propose a free liquid mercury surface as production target for the neutrino factory at CERN. In this design, the proton beam is injected through an annular nozzle collinearly into a free surface mercury-jet flowing with high axial velocity.

20.9
Enriched Isotopic Materials

To understand the interaction of two different materials, it is important to apply starting material that is as clean as possible, and not to add any impurities during the production process. Quite often, this is not enough. For a number of experiments, isotopically enriched targets or source material is needed. The most economic way is to buy these as the chemical compound required, with the desired enrichment. However, the suitable compound is not always available or the required compound is disproportionately expensive. Therefore one has to adapt chemical synthesis on a small scale with a high yield. In the early days of targetry, most of the metals were obtained by electrolytic methods. As this results in low compact material with intrinsic impurities, cleaning processes had to be added or alternative reduction methods had to be found, as discussed in the following sections.

20.9.1
Reduction with H_2

As described in any chemistry text book, heated metal oxides can be reduced by hydrogen. This technique gives good results and relatively clean metals even when applied on a small scale, which is typical for isotopical enriched materials. For reduction with hydrogen, the metal oxide is placed in a quartz tube in a furnace. During heating, a little hydrogen flow is streamed through the tube. Good results are obtained for oxides of Cd, Cr, Cu, Pb, and Zn. With this technique, metal of a good and pure quality, also suitable for cold-rolling processes, can be achieved (Manente and Blunt, 1995).

20.9.2
Reduction and Cleaning with the Hot-Wire-Iodide Process

Isotopically enriched Ti is mostly available as oxide. As it needs a highly reactive reductant, it can be reduced with Ca or CaH_2. The resulting material may contain up to 2% oxygen, so cold rolling is impossible. With the hot-wire–iodide process (Van Arkel–de Boer process) the titanium is converted into TiI_4, the gaseous compound is cracked at a hot tungsten wire, the metal deposits at the tungsten wire, and the gas is applied again for forming the metal iodide out of the metal. With this process hafnium, thorium, titanium, and zirconium can be cleaned so that the metal is rollable (van Arkel and van Boer, 1925). For isotopic titanium, the process is described by Maier (1979) in detail.

20.9.3
Reduction with Ca, Th, or C and Extra Cleaning

Often simple reduction processes leave intrinsic impurities in the required isotope. Quite often, an unacceptable amount of reductant or oxygen can be found in the foil, which makes the subsequent processes for the target production difficult or impossible. Spirlet, Müller, and van Audenhove (1985) describe the reduction of Pu with Ca, with Th, and with C. After the reduction they recommend either electrorefining or an extra evaporation and deposition of the material obtained. The following section combines these processes in one.

20.9.4
The Reduction–Distillation method

As direct reduction processes often show impurities of the reductant, a reduction and distillation process is a clean alternative. The isotopically enriched isotope and the reductant must have a significantly higher melting point and accordingly a very low vapor pressure in the temperature range in which the resulting isotopically enriched metal already shows a significant vapor pressure. So the mixture of the oxide and the reductant perform a solid–solid reaction, the oxide is reduced, and the resulting metal condenses on a water-cooled collector above the setup, as shown in Figure 20.7. Depending on the metal to be reduced, different reductants are used. This method has been primarily developed and discussed by Kobisk *et al.* at the ORNL (Kobisk and Adair, 1979;

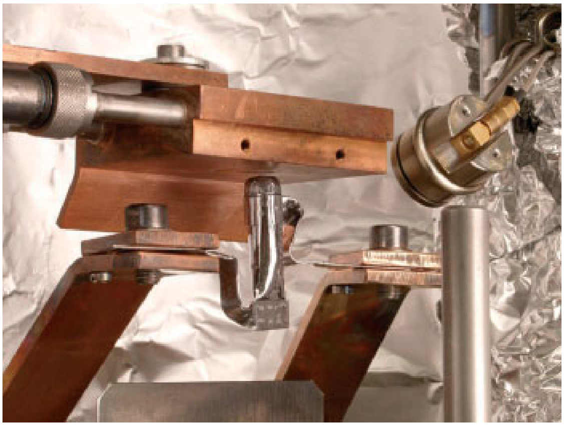

Fig. 20.7 ^{48}CaO mixed with Zr in a tantalum crucible. The reduced Ca is deposited on a water-cooled copper plate (Lommel *et al.*, 2006).

Kobisk and Grisham, 1969). They apply the technique for K, Ca, Sr, Ba, most of the rare earth oxides, Np, Pu, Am, and Cm. As reductants, they work with Ta, Zr, La, At, and Th. With this technique, pure isotopically enriched metal, with a yield of up to 92% and of a quality required for cold rolling, can be obtained. For each isotopically enriched oxide and the available amount of material, the process has to be optimized. For different materials, different reductants can be used. Today, Hf, La, and Zr are mostly the reductant of choice. The quality of the reductant, the size of the surface, and the enthalpy of both metal partners and the vapor pressure of both metals play an important role (Pengo *et al.*, 1991).

Marcus and Zevenbergen (1999) apply the reduction–distillation method with carbon as reductant, as known from steel production, for different zinc isotopes and obtain metal of good quality.

Sugai *et al.* describe the process of reducing the rare earth oxide via the fluoride. Then in an analogous process, calcium is applied to remove the fluorine and the metal is deposited on a cooled lid above the setup. Fairly clean isotopically enriched rare earth metal with a yield of 50–95% can be obtained (Sugai and Kato, 1985).

20.9.5
Chemical Compounds

In several situations where the isotope cannot be applied directly, compounds have to be used. The reasons are manifold: Sometimes, the compound is available more easily or is easier to produce in a target of the desired thickness; sometimes, the compound can be processed with a more favorable material consumption; and sometimes the applied compound shows a higher melting point or a lower sputter yield resulting in a better behavior in the beam as discussed in Section 20.6. In those cases, isotopic material has to be converted in the desired compound. Lommel *et al.* discuss the substitution of low melting metals. They replace lead by lead sulfide, and several rare earth metals by their fluorides. For this conversion of pure isotopic material, classical chemistry has to be adapted on a small scale for micro- or milligram amounts with a high yield under very clean conditions (Lommel *et al.*, 2006).

20.10
Characterization of Targets

The characterization of the target before application as well as after an irradiation is essential for the success and the accuracy of the experiment. The relevant parameters such as absolute thickness and homogeneity of the layer, variation in thickness across the active target area, and purity of the target have to be determined and controlled as accurately as possible. A survey of only the most commonly used methods is given in this chapter.

20.10.1
Thickness

The main parameter for a target is the absolute thickness of the layer. For most applications, weighing the substrate before and after the coating process is the most straightforward method to determine the target thickness in milli- or micrograms per square centimeter since this gives a direct measure for the number of nuclei interacting with a given beam diameter. In some cases, it may be not possible to determine the correct thickness of the target directly, for example, if the substrate is too heavy in relation to the target layer or if the target has to be coated additionally with a protective layer. When this is so, a dummy substrate can be measured that is either coated in parallel to the same process and is situated in an equivalent place with respect to the coating geometry or is coated in an extra process with equivalent conditions. Generally, balances of high accuracy are the workhorse for every target maker.

For an online measurement, oscillating quartz crystals are very commonly used as a monitor for evaporation or sputtering processes. They give a good qualitative idea of the achieved thickness, but for the determination of absolute thickness, a careful calibration is mandatory, as reported by Maier-Komor, Dollinger and Hammann (1991).

For thin targets that are transparent in visible or ultraviolet light, absorption with a spectrophotometer can be a fast method to measure the absolute thickness, provided that a prior calibration for the respective element was done. Lommel *et al.* (2002) discuss the accuracy of optical absorption and compare it with Rutherford backscattering measurements; the latter is a very accurate but rather complex method that is not applicable for daily quality control. Profilometers are the devices that have more commonly been in use during the last years for thickness determination of thin targets. They are suitable for very accurate measurements, but only on a very small scale.

For somewhat thicker layers, energy loss measurements with α-particles is a common method, as described, for example, by Alexander and Wirth (1985).

For radioactive targets, the radioactive decay itself can be detected either simply with a detector or with a radiographic imager, which gives a superior spatial resolution, as described by Liebe *et al.* (2008). The signals can be converted to a corresponding target thickness with a suitable calibration.

For bulk targets, the thickness can be measured with incremental length gauges with an accuracy of about 0.5 μm. In combination with an automatic setup, the thickness distribution of very large areas also can be measured with a high lateral accuracy, as reported by Kindler *et al.* (2002).

20.10.2
Purity and Homogeneity

In the first place, one has to make sure that the starting material is as pure as is necessary for the experiment and work in an environment that is as clean as possible. To prevent any contamination during the deposition process, the vacuum should be in the region of 10^{-7} hPa region, and attention has to be paid to the crucible material applied.

To check the appearance of the target layer and search for inclusions, holes, or other defects, optical microscopy is a method that is available in almost every laboratory. A more fancy but very powerful instrument is a scanning electron microscope that in combination with an energy dispersive X-ray analysis even allows for element identification, at least for impurities existing in the range of percent.

20.11
Outlook

In numerous accelerator facilities worldwide, the intensity of the beams available is increasing constantly and this has to be accompanied in equal measure by a target development. New concepts for the enhancement of target durability have to be found for future experiments to profit from the more and more intense beams, as was described in Sections 20.6 and 20.8. In this context, the label *high power target* has already found its way into literature.

The science and art of fabricating targets that are adapted to the experiment as optimally as possible remain a challenging task in the twenty-first century, and facilities dedicating manpower and funds to this task will secure a competitive advantage.

Acknowledgments

Special thanks to Klaus Eberhardt, Universität Mainz, Institut für Kernchemie, Fritz-Strassmann-Weg 2, D-55128 Mainz, Germany, who wrote Section 20.4, *Preparation of Targets by Electrochemical Deposition*. We thank Hartmut Reich-Sprenger from GSI, Vacuum Group for the Section 20.7, *Internal Targets*, and Robert Grisenti, Universität Frankfurt a. M., Institut für Kernphysik, Max-von-Laue-Str. 1, 60438 Frankfurt am Main for the Section 20.7.3 *Cryogenically cooled liquid targets*. We want to express our gratitude to John Stuart Winfield, GSI, for looking closely at the final version regarding English style and grammar, correcting both and offering suggestions for improvement.

INTRODUCTION

Polymers including plastics and elastomers are an important part of the world economy. They are widely used not only as final products but also as major components or modules in composite products such as automobiles. One sees fabricated polymer products in roles such as textile fibers, film for packaging and videotape, bottles, refrigerator liners, computer housings, automobile/truck/aircraft tires, automobile bumpers, and gasoline tanks.

It is our intention in this article to describe the development and status of polymer processing technology.

1. HISTORICAL OVERVIEW

Polymers have always been part of commercial and daily life to remotest antiquity in all civilizations. Cotton, wool, silk, leather, wood, and natural rubber are all polymeric materials that have been commercially fabricated into useful products from the dawn of civilization to the present. Some perspective is needed. Generally, the fabrication of textile structures from fibers such as cotton, wool, and silk is not classified as part of polymer processing but as textile processing. The shaping of wood and its conversion into paper is similarly classified as a technology distinct from polymer processing. The beginnings of modern polymer processing are generally considered to be associated with technologies arising from the introduction of natural rubber in large quantities into Europe and the United States from South America after 1815 and the introduction of gutta percha from Malaya after 1840. Processing operations including mastication, mixing, solution coating, and compression molding were practiced in the 1820s. The 1830s saw the invention of the two-roll mill and the four-roll calender by Edwin M. Chaffee. Progress accelerated in the 1840s with the introduction of vulcanization and the invention of injection molding, blow molding, and wire coating, which were applied to rubber and naturally occurring gutta percha. These inventions are associated with Charles Goodyear and the brothers Thomas Hancock and Charles Hancock.

The 1860s saw the introduction of cellulose nitrate, the first man-made polymer, into industry. This led to major advances in molding technology, which are largely associated with John W. Hyatt and his brother Isaiah S. Hyatt. Cellulose nitrate was developed into the first commercial man-made fiber by the Count de Chardonnet by extruding small-diameter filaments of its solution through spinneret dies. In one process developed by Chardonnet, the filaments were coagulated by extruding them into a suitable

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

liquid bath (wet spinning), and in a second they were extruded into an air stream that evaporated the solvents (dry spinning).

The screw extruder was first introduced to the polymer industry in the 1870s. It was first applied to wire coating with gutta percha and subsequently used for extruding profiles from natural rubber compounds. The early screw extruders, like the roll mills and calenders, were steam heated.

The twentieth century saw the development of totally synthetic polymers. Both synthetic rubber and synthetic plastics were developed by chemists by the 1930s. These included synthetic thermosets, such as Leo Baekeland's Bakelite®, and melt-processable thermoplastics including polystyrene and polyvinyl chloride. These two new polymers had much higher melt-processing temperatures than rubber or gutta percha, as did other polymers that soon were developed, including polymethyl methacrylate, polyethylene, polyamide-66, and polyamide-6. The 1930s and early 1940s saw the development of electrically heated screw extruders for these polymers. The late 1930s saw the invention of screw injection molding machines for rubber compounds and the early 1940s for thermoplastics. The first twin-screw extruders were commercially developed in Germany and Italy in the late 1930s and early 1940s.

The post World War II period witnessed the development and expansion of polyolefins. The branched low-density polyethylene of the 1930s was supplemented in the 1950s by linear high-density polyethylene and stereoregular isotactic polypropylene. Polyethylene terephthalates were introduced in the early 1950s. The 1940s and early 1950s also saw the development of rubber-modified or high-impact polystyrene (HIPS) and rubber-modified acrylonitrile–styrene copolymers (ABS resins). The end of the decade saw the introduction of tough transparent polycarbonate.

The period following World War II has also seen great advances in polymer processing technology. Single-layer plastic film, largely produced by a tubular film extrusion using air inflation, has become an important industrial process, largely based upon low-density polyethylene. Multilayer film extrusion using polymer melt streams from three or more extruders to produce film has become increasingly important. Biaxially stretched films are made primarily from polyethylene terephthalate by first extruding film from a slit die onto a chilled roll and from there onto a tentering frame where films are stretched biaxially at controlled rates and temperatures. Modular twin-screw extruders were developed for compounding.

Screw-injection molding has become the most important plastics processing operation in terms of numbers of machines and employment. However, other molding processes have also become important. Thermoplastic bottles are today produced by different molding processes in which injection-molded preforms are inflated with pressurized air and pressed into molds.

2. PROPERTIES OF POLYMERIC MATERIALS AFFECTING PROCESSING

2.1 General

Generally, thermoplastics and elastomers are processed in the molten state. It is first necessary to describe the structural and thermal characteristics of polymers. The thermal transition characteristics are largely independent of molecular weight, when such molecular weights exceed the so-called entanglement transition value (which is needed to achieve desirable mechanical properties). Many important commercial thermoplastics are largely crystalline and exhibit moderately strong melting transitions. These include the following (where the first parentheses contain a commonly used acronym for the polymer and the second parentheses indicate melting temperatures): high-density polyethylene (HDPE) (T_m = 135 °C), isotactic polypropylene (PP) (T_m = 165 °C), polyamide-6 (PA-6) (T_m = 215 °C), polybutylene terephthalate (PBT) (T_m = 220 °C), polyethylene terephthalate (PET) (T_m = 260 °C), polyamide-66 (PA 66) (T_m = 260 °C), poly *p*-phenylene sulfide (PPS) (T_m = 285 °C), and polyether ether ketone (PEEK) (T_m = 340 °C). Other important commercial polymers do not crystallize but rather vitrify into glasses. Here the glass transition temperature T_g is relevant. Important vitrifying thermoplastics include polystyrene (PS) (T_g = 100 °C) and polycarbonate (PC) (T_g = 140 °C).

Crystallizing thermoplastics can be melt processed at temperatures slightly (≥20 °C) above their melting points, but for vitrifying thermoplastics one must be roughly 80 °C or more above their glass transition temperatures.

2.2 Melt Flow

Unlike thermal characteristics, the rheological or melt flow properties of polymers are very dependent upon molecular weight and its distribution. Generally, the viscosity in shear flow is constant at low shear rates and decreases with increasing shear rate. The zero-shear viscosity η_0 of a linear polymer increases with the 3.4 power of molecular weight, above the entanglement transition. For polydisperse polymers the molecular-weight dependence is through the weight-average molecular weight M_w. Specifically,

$$\eta_0 = \mathrm{K} M_w^{3.4}, \tag{1a}$$

where

$$M_w = \frac{\sum w_i M_i}{\sum w_i} = \frac{\sum N_i M_i^2}{\sum N_i M_i}. \tag{1b}$$

Here N_i refers to numbers of molecules and w_i to weights or masses of polymer.

At higher shear rates where the viscosity decreases, it was found later by Vinogradov and Malkin that the reduced shear viscosity $\eta(\dot{\gamma})/\eta_0$ is independent of temperature and may be represented as a product of zero-shear viscosity times shear rate, i.e. $\eta_0\dot{\gamma}$. However, the functionality is sensitive to the breadth of the molecular-weight distribution (as measured by the ratio of different moments of the distribution, M_w/M_n or M_z/M_w):

$$\frac{\eta}{\eta_0} = F(\eta_0\dot{\gamma}, M_w/M_n \text{ or } M_z/M_w), \tag{2a}$$

where M_n and M_z are the number- and weight-average molecular weights,

$$M_n = \frac{\sum N_i M_i}{\sum N_i}, \quad M_z = \frac{\sum N_i M_i^3}{\sum N_i M_i^2}. \tag{2b}$$

At high shear rate, the shear viscosity is a decreasing function of shear rate on a logarithmic plot:

$$\eta = K\dot{\gamma}^{n-1}, \tag{3}$$

where n is a constant called the power-law exponent. Over the entire shear rate range, an expression such as

$$\eta = \frac{\eta_0}{1 + (\eta_0/K)\dot{\gamma}^{1-n}}, \tag{4}$$

would seem more appropriate.

A few words on the experimental determination of shear viscosity are necessary. At high shear rates, i.e. $\dot{\gamma} > 10\ \mathrm{s}^{-1}$, measurements are usually made in a capillary extrusion instrument. At lower shear rates, 0.01 to 1.0 s^{-1}, the cone-plate geometry is generally used. Here the polymer melt is usually tested in a nitrogen atmosphere to protect it from degradation. If lower shear rates are of concern, drag-flow sandwich or cylindrical (Pochettino) instruments are used.

Other rheological responses of polymer melts have been made and used to interpret processing behavior. These include

1. transient shear stresses at the startup of shear flow;
2. normal stresses, a nonlinear tensile stress effect that occurs in polymer melts in shear flow;
3. stress responses to oscillatory shear flow;
4. elongational viscosity arising from uniaxial extension measurements, and
5. stress relaxation.

It must be noted that many industrial polymer materials contain large amounts of fillers such as carbon black (in the case of rubber compounds) and (for thermoplastics) glass fibers and minerals such as talc, mica, and calcium carbonate. The addition of such materials can substantially increase the melt viscosity of the system. For compounds with more than a volume fraction of 0.15 carbon black or other submicron mineral particles, yield values develop. This means that the shear viscosity increases to infinity at a finite shear stress. At stresses below the yield value, there is no flow.

2.3 Orientation and Solidification

When cooled from melt as indicated above, many polymers (polyethylene, polypropylene, polybutylene terephthalate) crystallize. Other polymers (polycarbonate, polystyrene) vitrify into glasses. Some polymers (e.g., polyethylene terephthalate, polyphenylene sulfide) can vitrify or crystallize depending upon rates of cooling and states of stress during processing. The latter type of polymers often undergo two-stage processing, in which they are preshaped in a vitrified form and then undergo a second-stage processing in which they are shaped and crystallized.

Polymers are long-chain molecules. During processing, these chains can orient. Usually such orientation is in directions determined by applied stress fields. Thus if a filament is formed and uniaxially stretched, a state of uniaxial polymer chain orientation is developed along the direction of the filament axis. If a film is formed by biaxial stretching, the applied stresses tend to create a state of biaxial orientation in the plane of the film.

3. PROCESSING OPERATIONS

3.1 General

Following polymerization, polymers generally proceed through a series of processing operations before achieving their final product state. These include

1. post-reactor processing to remove volatiles and to introduce stabilizers;
2. compounding with fillers, reinforcing agents, and colorants to prepare the polymer for its final application;
3. molding or extrusion of the polymer melt to form final form; and
4. post-die processing in extrusion operations wherein extrudates are further shaped, such as inflation of melt emerging from annular dies to form a thin film (tubular film extrusion) or into bottles (extrusion blow molding).

In post-reactor processing, extrusion, and molding operations, there is a common usage of a screw, which occurs in all of the processing machines. Machines for producing profiles, extrusion blow molding, injection molding, post-reactor processing, and continuous compounding all contain screws. Usually, shaping machines involved in profile extrusion or molding operations use single screws. Profile extrusion of polyvinyl chloride for pipe and window profiles is, however, often carried out with intermeshing counter-rotating twin-screw extruders. Continuous compounding and post-reactor processing are usually carried out in modular corotating twin-screw extruders, but counter-rotating twin-screw machines are also used.

The screw principle is basic to polymer processing operations and deserves separate treatment. A screw is a steel shaft with a helical spine winding about its axis (Fig. 1). In a single-screw extruder, as the screw rotates in a barrel, the friction exerted on the material between the screw flights causes it to advance around the helix and move axially toward the die. Single-screw extruders are generally plasticating devices, in which thermoplastics are introduced into the entrance (or hopper) of the extruder and are conveyed toward the die. Barrel heating and pressurization leads to the initiation of melting, which is greatly enhanced by viscous dissipation of the highly viscous polymer as it is forced to flow. Generally, screws for single-screw extruders have deep channels in the feed/hopper region and tapered screw root diameters in the melting region. In the region nearest the die, known as the metering region, the screw channel is shallow. Often to enhance extruder productivity, the barrel in the solid conveying region is grooved to increase friction and pressure development.

Turning to twin-screw extruders (Fig. 2), self-wiping corotating twin-screw extruders and tangential counter-rotating twin-screw extruders are also drag-flow pumping machines. Fully intermeshing counter-rotating twin-screw machines are positive-displacement pumps.

3.2 Polymer and Compound Preparation

The first steps following polymerization, as described earlier, are post-reactor processing, carried out by a resin manufacturer, and compounding that may be carried out by either a resin manufacturer or a separate company usually called a compounder. The two processes are similar and are usually carried out in twin-screw extruders or in other complex mixing machines such as the Buss

Kneader in which an interrupted screw oscillates axially and rotates within a barrel containing inwardly projecting teeth.

Most important are modular self-wiping corotating twin-screw extruders (Fig. 3). These machines have modular screws and a modular barrel construction. The machines have two parallel shafts with a fixed distance between them. Pairs of identical elements are placed on the two shafts until the shafts are totally filled. These elements are right-handed (forward pumping) screws, left-handed (backward pumping) screws, and various types of mixing elements, notably kneading discs. Twin-screw extruders generally have multiple feed parts so that polymers, stabilizers, and reinforcing agents may be introduced into different feed parts.

Modular intermeshing counter-rotating and tangential counter-rotating twin-screw extruders are also used for compounding. The intermeshing machines exhibit high levels of shear stress and are very good dispersive mixers for pigments. Tangential counter-rotating twin-screw extruders have large volumes for a given screw diameter and are often conveniently used for devolatilization and reactive extrusion.

3.3 Shaping: Extrusion

One of the most important shaping operations is the manufacture of continuous profiles, pipe, and tube from thermoplastics. Either a single-screw or a fully intermeshed counter-rotating twin-screw extruder is used to plasticate the polymer and generate the pressure required for extrusion through the shaping die. The dies used to form profiles must be specifically designed to ensure uniform distribution of the melt to the die so that uniform extrudates (or extrudates of desired design) are obtained.

We have seen increasingly through the years the development of multilayer extrusion, where the feeds of polymer melts from several different extruders are combined in a die. The most important product produced in this way is multilayer film, which is widely used for packaging. Generally at least five melt layers are required in such a process. There are two outer layers on the surface of the film or sheet, a core layer (usually a barrier material) and two adhesive layers

Orifice Plugs
Kneading Paddles

FIG. 3. Modular co-rotating twin-screw extruder.

that bind the external film surfaces to the core. The five melt layers may be seen to involve these materials: core, adhesive, and outer layer.

3.4 Shaping: Post-Extruder Processing

In some important processing operations, extrudates continuously emerging from dies are further shaped by applied tensions and pressures. Thus, extrudates emerging from dies are drawn down by applied tensions to form greatly reduced cross sections (Fig. 4). This is notably the case in melt spinning of molten polymers such as poly(ethylene terephthalate), polyamide-6 (and -66), and polypropylene to form continuous filaments or fibers. The take-up velocities today are quite large, being many thousands of meters per minute. Associated with the high velocities are high draw-down ratios and high spinline tensions. Generally the dies have a very large number of small orifices so that numerous filaments—a yarn—and not a monofilament are produced. The design of such dies, known as spinnerettes, is quite complex because of the problem of uniformly distributing polymer melt.

A second polymer processing operation that involves post-extruder processing involves the manufacture of film by the tubular blowing process (Fig. 5). Generally a thin annular tube is extruded vertically upward. This tube is both inflated with pressurized air and drawn down by applied tensions. The tubular film process is most widely used with low-density polyethylene.

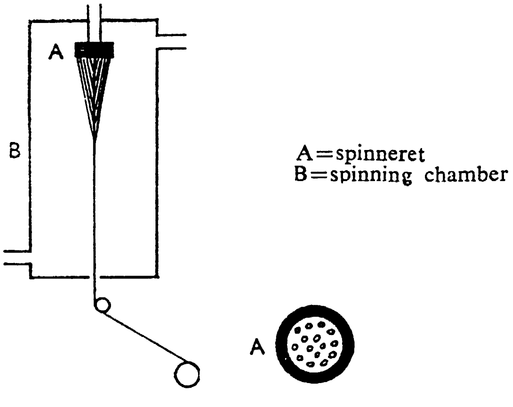

FIG. 4. Melt spinning of filaments.

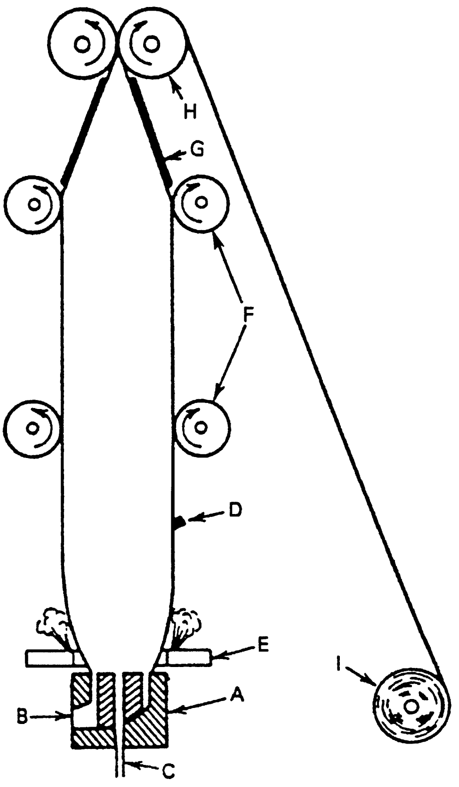

FIG. 5. Tubular film process for extrusion of blown film. A, blown-film die; B, die inlet; C, air hole and valve; D, plastic tube (bubble); E, air ring for cooling; F, guide rolls; G, collapsing frame; H, pull rolls; I, windup roll.

In addition to the tubular film process described in the above paragraph, double-bubble tubular film processes have been developed and used commercially. The first of the two bubbles is used to shape the film. The second of the two bubbles biaxially stretches the film in a controlled environment, generally both developing biaxial orientation and crystallizing the melt. This process was first devised for polyvinylidene chloride by Dow Chemical but has subsequently been used notably for polypropylene and polyamide-6.

Film may also be produced by slit dies that extrude vertically downward onto rotating, chilled rolls. It is possible to convert such "cast film" to biaxially oriented film by means of a tentering frame. This apparatus mechanically grasps the edges of film during passage through a controlled-environment oven. The film is usually stretched uniaxially in different directions by stages.

3.5 Shaping: Molding

The most important of polymer processing operations is the manufacture of discrete thermoplastic, rubber, and thermoset parts. This general technology is called molding. There are many variations of molding technology.

The simplest type of molding technology is compression molding, where the polymeric material is placed in an open mold. This technology is generally applied to elastomers and thermoset materials. The upper (male) portion of the mold is then moved into place. The mold is heated and the material placed into the cavity softens and flows out radially under the pressure of the moving member to fill the mold. This flow is usually considered shearing in character. Once the mold is filled, the polymer solidifies through chemical cross-linking for elastomers and thermosets. For thermoplastics, solidification requires cooling the mold. When the polymer is solidified, the mold is opened, the part removed, and the process repeated.

In injection molding, which is primarily applied to thermoplastics, a polymer is melted and pressured, usually with a rotating screw, and then injected into a mold by the reciprocating motion of the screw (Fig. 6). In thermoplastic injection molding, the mold is cold and solidifies the melt filling it. In injection molding of rubber compounds, the mold is maintained hot, and the rubber is vulcanized when it fills the mold. After solidification the mold is then opened and the molded part removed. The process is then repeated.

In rotational molding, a thermoplastic powder is introduced into a mold. The mold is then rotated biaxially in an oven. The powder melts and coats the surface of the mold. The mold is then moved to a quench chamber where it is cooled by water shower or mist. The mold is subsequently opened and the molded part removed. Generally, rotational molding produces hollow parts. It has a longer production cycle than blow molding, but the equipment is simpler and easier to construct.

In blow molding (Fig. 7), a screw extruder and die are used to produce an annular polymer melt sheet, known as a parison, which is extruded vertically downward. A mold of a bottle then closes around the parison, and air is injected into the melt parison until the melt fills the mold. The mold is cooled, the melt solidifies, the mold opens, and the fabricated bottle is ejected.

Stretch-blow molding is a two-stage molding process developed originally for polyethylene terephthalate. Tubelike preforms are first injection molded and extruded. These are noncrystalline glassy in character. The preforms are introduced into the stretch molding machine where the temperature is raised above T_g. The preform is then inflated (often with the aid of a moving mandrel) to fill the mold. During the mold filling, the inflating preform polymer develops biaxial orientation and crystallizes.

3.6 Computer-Aided Engineering

It is possible to model mathematically to varying extents the various polymer processing operations. In many cases such modeling

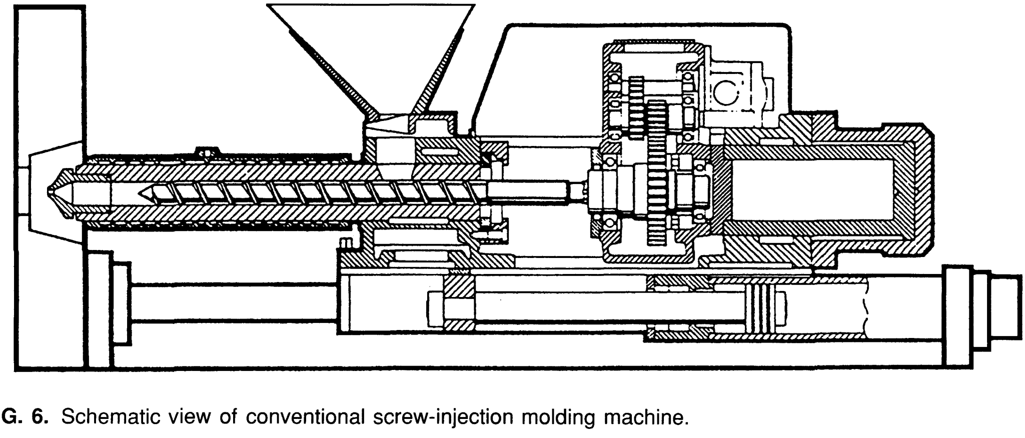

FIG. 6. Schematic view of conventional screw-injection molding machine.

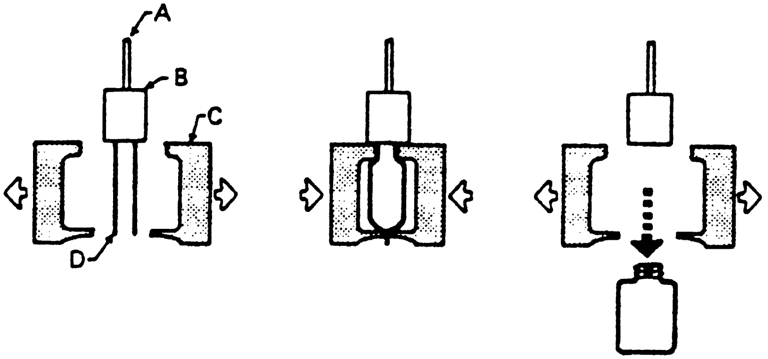

FIG. 7. Blow molding. A, air line; B, die; C, mold; D, parison.

is highly useful as it can provide information on the detailed behavior of melt flows in molds, dies, and extruder screws. Many of these models have been converted into user-friendly computer software, which is marketed by firms all over the world.

Probably the earliest activities of this type involved melt spinning of synthetic fibers and were the result of activities of Kase, Matsuo, and their co-workers with Toyobo in Ohtsu, Japan. At about the same time, Tadmor and Klein with Western Electric and later Scientific Process and Research developed simulations and software for flow in plasticating screw extruders.

More successful than these activities were modeling efforts of the late 1970s and 1980s directed toward injection-mold filling and later packing and residual-stress effects. In the 1970s, various researchers presented simulations of mold filling. Colin Austin founded the firm Moldflow-Australia. In later years, extensive activity has been given to simulation of flow in dies, blow molding, and other processing operations. The development of special finite-element packages such as "FIDAP" and "Polyflow" have allowed individual engineers to do calculations. These have been applied to problems ranging from die design to blow molding. Modular corotating twin-screw extruders have been simulated in the 1980s and 1990s, and software is available from The University of Akron and the University of Paderborn.

Such simulations are based upon solving the basic force-balance, energy-balance, and continuity equations of continuous mechanics together with suitable constitutive equations for the deforming polymer melt. Constant density is usually assumed. As the viscosity levels of polymer melts are very high, one usually neglects inertial force terms. The basic balance equations are force balance,

$$0 = \nabla \cdot \boldsymbol{\sigma}; \tag{5}$$

energy balance,

$$\rho c\left[\frac{\partial T}{\partial t} + (\mathbf{v}\cdot\nabla)T\right] = k\nabla^2 T + \sum_i \sum_j \sigma_{ij}\frac{\partial v_i}{\partial x_j}; \tag{6}$$

and continuity,

$$\nabla \cdot \mathbf{v} = 0, \tag{7}$$

where $\boldsymbol{\sigma}$ is stress, T temperature, $\mathbf{v}$ velocity, and k thermal conductivity. The constitutive equations used usually have the form

$$\boldsymbol{\sigma} = p\mathbf{I} + 2\eta(\operatorname{tr}\mathbf{d}^2, T)\mathbf{d}, \tag{8}$$

where $\mathbf{d}$ is the rate-of-deformation tensor, p is pressure, and tr $\mathbf{d}^2$ is the sum of the diagonal components of the matrix $\mathbf{d}^2$. Equation (8) represents polymer melts as viscous non-Newtonian fluids. There have also been efforts to include viscoelastic effects in constitutive equations to solve processing problems. However, no consensus exists on how to do this.

Most analyses of processing equipment, especially for dies, injection molds, and extruder screw channels, use hydrodynamic lubrication theory in which Eqs. (5) and (6) are simplified to force balance,

$$\begin{cases} 0 = -\dfrac{\partial p}{\partial x_1} + \dfrac{\partial}{\partial x_2} \eta \dfrac{\partial v_1}{\partial x_2}, & \text{(9a)} \\ 0 = -\dfrac{\partial p}{\partial x_3} + \dfrac{\partial}{\partial x_2} \eta \dfrac{\partial v_3}{\partial x_2}, & \text{(9b)} \end{cases}$$

and energy balance,

$$\rho c\left[\frac{\partial T}{\partial t} + v_1 \frac{\partial T}{\partial x_1}\right] = k \frac{\partial^2 T}{\partial x_2^2} + \eta\left[\left(\frac{\partial v_1}{\partial x_2}\right)^2 + \left(\frac{\partial v_3}{\partial x_2}\right)^2\right], \tag{10}$$

and the shear viscosity η is considered to be nonisothermal and non-Newtonian, depending upon T and tr $\mathbf{d}^2$ through:

$$\eta = F\left(\left(\frac{\partial v_1}{\partial x_2}\right)^2 + \left(\frac{\partial v_3}{\partial x_2}\right)^2\right) \exp[-B(T - T_0)], \tag{11}$$

where the functionality might be that of Eqs. (3) and (4). Such simulations may be used to design injection molds by considering the influence of the design of cooling channels in molds on melt filling.

In more recent years, mold design methods (including computer software) have allowed the calculation or better estimation of residual stresses and warpage of parts removed from molds. Such developments allow the problems of part design and mold design to be treated.

4. PART DESIGN

Thermoplastic and thermoset molded parts developed a "bad name" in the early years of the polymer industry. This was because parts were badly designed, with designers generally not recognizing that the polymers they were dealing with had lower Young's moduli and failure stresses than the metals they were replacing.

It is desirable to use design procedures that take into consideration not only the mechanical properties of the polymeric materials used but the thickness of sections and cross-sectional moments of inertia. While correct design procedures based on the theory of elasticity have always been available during the life of the polymer industry, they have frequently been ignored. It is only in recent years that computer-aided design procedures have been developed to accomplish this and attention has been given by engineers to these problems.

5. FUTURE OUTLOOK

Any view to the future of polymer processing technology must envisage the manufacture of more complex polymeric parts, which will be produced with greater precision. Greater complexity will involve on the material side sophisticated polymer structures, and better controlled molecular-weight distributions and types of branching. On the machine side, one will see processing machinery, especially injection molding machines, that will be able to produce "engineering parts" with more precise dimensions and with multiple components.

To a growing extent the future is already with us. The newer-generation Ziegler–Natta catalysts known as "metallocenes" are producing polyolefins with more controlled structures. Injection-molding technologies exist that produce engineering parts with more precise dimensions have been developed. This is accomplished by greater control of the *PVT* characteristics during the cooling cycle to limit shrinkage and warpage. In "gas-assist injection molding," hollow molded parts with carefully located void regions are developed. This allows the development of parts containing not only less material but lower residual stress. More industrially molded products contain inner layers that give greater barrier protection in packaging or contain recycled materials. Molding technologies exist where different thermoplastics and elastomers (usually thermoplastic elastomers) may be combined together in a single mold to give parts with both hard and soft sections.

INTRODUCTION

"Telecommunications" means communication at a distance. While pigeons, human couriers, written messages, and sound systems of various sorts have been used for distance communications for millennia, the vehicle of rapid, long-distance communication is almost exclusively electromagnetic, ranging from very low-frequency radio for submarine communication to light in optical fibers.

We can do worse than start with Shannon. Figure 1, based on the famous figure by Shannon (1948), is a schematic communication model for a source seeking to communicate a message, *M*, to a destination over a communication channel. The rest of this article consists of elaborations or generalizations of this simple model.

To fix ideas, let us consider an example of a message being left in a voice-mail system. The originator of the message might speak the message into a microphone. The micro-

digital Encyclopedia of Applied Physics

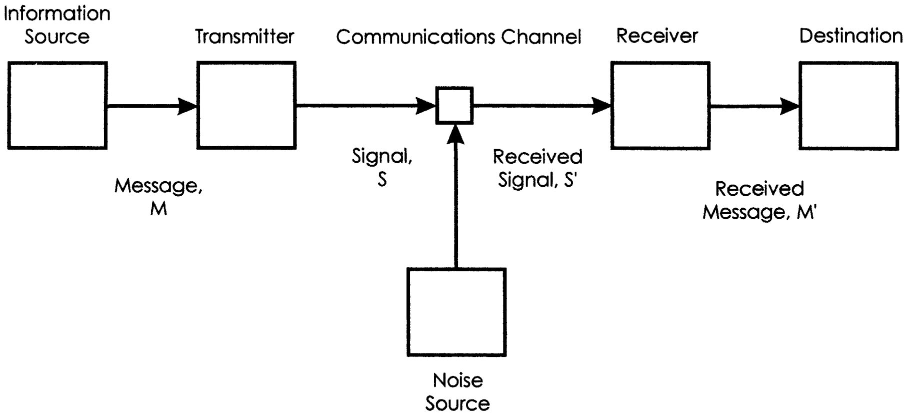

FIG. 1. Schematic diagram of a general communication system.

phone converts the acoustic waves of the speech into an electrical analog *message*. We will consider the acoustic message to be external to our system so that the *information source* is the microphone and the *message* is the electrical wave form from the microphone. Quite often, the message is converted from the analog electrical message into a digital form at the transmitter. The resulting digital signal, *S*, is sent over a communication channel. At the other end of the channel, the receiver, *R*, receives a signal, *S'*, which, it is hoped, represents faithfully the sent signal *S*. This will not always be the case because of possible noise in the system. The received signal is then decoded into a received message, *M'*, which, in this case, is still digital so that the message can be stored in the computer for later retrieval.

To preview the ensuing discussion let us consider the process illustrated by Fig. 1 in more detail. The first issue is how to characterize the "message". Some of the aspects that need to be addressed is how much communication capacity various types of messages require and how the communication requirements vary in time. These are addressed in Sec. 1. One can also say much about the conversion from the initial message *M* to the transmitted signal *S*. There are, potentially, three objectives in this transformation. The message may be *compressed* in order to use less channel capacity; on the other hand, additional redundant information may be added to enhance the ability to detect errors and, in some cases, even to correct them. Finally, the signal is converted to a form that is appropriate to the channel being used. The first two points are addressed in Sec. 3.3; the last point, in Sec. 2. The "channel" may be a simple point-to-point channel such as a wire pair or optical fiber, it may be a broadcast transmission facility such as a radio or satellite channel, or it may be derived from a complex network of facilities shared with other users. In either case, various techniques are used to gain efficiencies. We discuss the techniques that are applied to individual channels in Sec. 3 and the techniques that apply to networks of shared facilities in Sec. 4. The physical properties of the basic transmission facilities are then treated in Sec. 5. "Noise" in this simple model represents all the various phenomena that can interfere with communication. This includes noise in the narrow sense, such as thermal noise, as well as echos, distortions of various sorts, and even deliberate interference such as jamming in military applications. Despite the form of Fig. 1, noise and other transmission impairments can arise in the receivers and transmitters as well as the channel. For example, in space communication, receiver noise is very important. Issues dealing with communication impairments for wireless channels are addressed in Sec. 5.1.1, and for constrained media, in Sec. 5.2.1.

We end our article with Sec. 6, which provides a few remarks on the future of telecommunications technology.

1. APPLICATIONS

Information can be analog or digital. Communication capacity is measured in terms of bandwidth for analog communication and by data rate for digital communication. A simple relation between the two was given by Shannon (1948):

$$C = W \log_2(1 + S/N),$$

where C is the highest data rate that can be approached on a channel with bandwidth W with signal power S and noise power N (assumed to be white).

The message or information that is sent in communication systems can be characterized as one of four categories or *services:* voice, data, image, or video. It is useful to have a rough idea of the relative magnitudes of the communication capacity required by the four basic services. Since most modern telecommunications systems deal with information in digital form, we give our estimates in that form, even for information such as voice, which is intrinsically analog.

The most common example of data services is the communication of text, and numerical information. Typically, in a communication system, an individual alphanumeric character is represented by a byte or an octet (8 bits). So, for example, representing an A4 size, single-spaced page of text would require about 3500 octets.

Images can basically be represented digitally in two ways. The most straightforward way is by a *bit map.* The image to be communicated is divided into a rectangular grid. The intersections on the grid are represented by pixels (picture elements). Associated with each pixel is a color and/or intensity value. For black and white high contrast images, the "value" consists of only one bit representing black or white. A black and white bit map with a gray scale, using, say, b bits per pixel can be used to represent 2^b values ranging from white through gray to black. For color, a variety of schemes can be used to represent the color at the pixel. One straightforward way is to assign three equal-sized groups of bits, one for each of three primary colors to characterize the color as a mix of the three primary colors.

Consider a typical laser printer that might print 300 pixels per inch in the vertical and horizontal directions or 90 000 pixels per square inch. To represent the same A4 sheet of paper as before, except this time as a bit-mapped image, would require about 7 500 000 bits. In general, however, there is much redundancy in an image that can be taken advantage of in communication. For example, often in documents there are large areas of white space that can be summarized by coding rather than by sending large numbers of identical pixel representations. Moreover, there are more efficient ways to *send* the image to the printer than by a bit map. This brings us to the second representation of images. Rather than specifying the image at each of the pixels, we can give instructions on how to draw the image. For many types of images, for example, Fig. 1 of this article, these instructions can be encoded to communicate the image much more efficiently than by using bit maps. To print, the laser printer then carries out the "instructions" it receives to obtain a bit map for printing. In either case, the number of bits required to represent an image is typically many times that required by a data message representing the same information.

Voice is another important class of communication application or service (we also often include in this category communication of music and other sounds). Voice is an intrinsically analog source, but in modern systems it is typically communicated by digital signals. As with images there are two approaches to representing voice digitally: a conceptually simple scheme that is relatively expensive of channel capacity and a more complicated approach that can be used to reduce communication requirements. The analog of a bit map for images is simply to sample the voice (at a rate higher than twice the bandwidth to avoid aliasing), discretize the resulting samples, and then represent each sample's amplitude by a given number of bits. This is called *pulse code modulation* (PCM) and is commonly used for telephone voice. For telephone quality voice, one commonly assumes a bandwidth of less than 4000 Hz. The voice signal is sampled at 8000 times a second, and the signal amplitude of each sample is represented by an 8-bit octet. This results in a source rate of 64 000 bits per second (bps). As another example, sound on a music compact disc (CD) is sampled at 44 100 times per second, and 16 bits are used to represent the amplitude of each sample. The sound is stereo, and so we have two such sources of bits. Thus the total rate is 2 × 44 100 × 16 = 1 411 200 bps. Telephone-quality voice can be communicated using data rates that are $\frac{1}{2}$ or $\frac{1}{4}$ or less of the source rate of 64 000 bps by use of various compression schemes. Even lower rates can be used if a different strategy that takes into account the specific nature of the vocal tract is used. Such compression schemes—for example, linear predictive coding—are used to make efficient use of the broadcast spectrum for digital mobile telephony. By means of such techniques, recognizable, if relatively poor quality, speech can be communicated at rates in the neighborhood of 2400 bps.

For video, there is again a straightforward form and a more complicated yet efficient form. The straightforward form is to simply send a number of "bit maps" per second (in the range from 26 to 30 per second). The required communication capacity is formidable even using high-capacity fiber-optic transmission facilities. To be practicable, substantial compression is needed. The compression process is aided by the fact that, in addition to the geometric redundancy inherited from the individual bit-map images, there is also temporal redundancy in the sense that many of the successive images share much. Nevertheless, the compression required is so extreme that, typically, lossy compression is needed; see Sec. 5.3.1.2. A potentially more efficient form of video is to send drawings rather than bit maps. This form is usually called *animation.*

The variation in time of the arrival of bits generated by a message or sequence of messages is also important. For some types of communication the arrival of bits from the source is relatively constant, or *smooth*—for example, the sending of long files, or the sending of uncompressed digital voice. Other types of traffic are much more erratic, or *bursty.* For example, traffic generated by a human-operated terminal can be quite erratic with long (in electronic terms) periods of inactivity while the terminal operator ponders his/her next operation, followed by bursts of activity, say when the terminal receives a bit-mapped image. We can characterize the *burstiness* of traffic in various ways; one convenient way is in terms of the ratio of the peak data rate of the source to its mean rate. As we shall see, bursty traffic is best carried with completely different system architectures than for nonbursty traffic.

Messages in different applications often have differing fidelity measures or figures of merit. An important distinction here is the difference between real-time traffic and non-real-time traffic. Examples of real-time traffic include voice conversations and video conferencing. Such applications are sensitive to delay and, even more importantly, to variations in delay (jitter). The accuracy and even the arrival of individual message elements is relatively less important. On the other hand, for non-real-time applications such as data communication, accuracy is often paramount, so much so that if the message does not arrive correctly the first time, the relevant message is retransmitted. Real-time traffic often does not permit this luxury.

2. DIGITAL AND ANALOG TRANSMISSION

Both information and the representation of the information for transmission as signals can separately be digital or analog. This allows four possible combinations that we consider in turn.

We can encode digital information as an analog signal, we can digitally encode analog signals, digitally encode digital data, and encode in analog form analog information.

2.1 Analog Encoding of Digital Information

Analog encoding of digital information is called *modulation.* The device that performs the coding and decoding is called a *modem* (modulator-demodulator). The basic idea is to modulate or perturb a *carrier* sine wave. This can be done by varying each of the three defining parameters of the sine wave: the amplitude, the frequency, and the phase. The results are, respectively, *amplitude-shift modulation, frequency-shift keying,* and *phase-shift keying.*

Each change of the amplitude, frequency, or phase, respectively, is a signal element. For example, the phase may be shifted to one of four different values. Thus the signal element can have four realizations or 2 bits per signaling element. One should carefully distinguish between the *signaling* rate, which is measured in baud, and the data rate, which is measured in bits per second. So in the previous example, if the signaling is at 1000 baud, the data rate would be 2000 bps because each signaling element corresponds to 2 bits.

Notice that, for virtually all wireless communication of digital data, an analog encoding must be used since transmission can only take place at relatively high frequencies (using a carrier) compared to most digital information signaling rates. Similarly, communication of digital information over a fiber-optic link is usually amplitude-shift keying because the basic frequencies of light, around 10^{14} Hz, are much higher than any information data rates used today. Otherwise, amplitude-shift keying is rarely used except in combination with other modes because it is rather inefficient and is sensitive to sudden gain changes that commonly occur.

Combinations of amplitude-, frequency-, and phase-shift keying can be used as well. This approach is common for all but the lowest-performance modems. A combination of amplitude- and phase-shift keying is common and is called *quadrature amplitude modulation* (QAM). The *signaling constellation* or group of possible signal realizations can be plotted on a polar graph where the angle represents the phase shift and the radius, the amplitude of the realization. In practice, a signaling scheme with 16 possibilities (4 bits) might be used with a signaling rate of 2400 baud to produce a 9600-bps modem.

2.2 Digital Encoding of Analog Signals

We have discussed previously several advantages of digital transmission over analog. With the advent of the microprocessor in the late 1960s and early 1970s, digital transmission could be cost-effectively implemented. Some of the advantages of digital transmission are these:

1. The use of regeneration rather than amplification reduces the propagation of noise on the signal path.
2. Digital signals can be much more effectively routed, encrypted, and compressed.
3. More effective error control procedures are possible—e.g., cyclic redundancy checksums (CRCs).
4. Digital signals can be more effectively multiplexed [time-division multiplexing (TDM) is more efficient than frequency-division multiplexing (FDM)].

Thus since the early 1970s the transmission systems of choice have been digital. This makes it necessary to convert voice information and other analog information to digital signals. The most common method is pulse code modulation (PCM). The device that accomplishes this conversion is called a *codec* (coder-decoder). The conversion from analog information to digital signal by this method is a two-part process.

We assume that the information signal has a bandwidth of W. For telephone voice, W is between 3 and 4 kHz. For compact discs, $W = 22\,050$ Hz. The Nyquist sampling theorem tells us that if we sample an analog signal with bandwidth W at a rate of $2W$ or more samples per second, then the original signal can be reproduced exactly from the samples. Note that after this process, the samples are still analog; that is, they can take on a continuum of values rather than a discrete number. This part of the conversion is reversible with complete accuracy. Sometimes this sampling is used as a multiplexing method by itself without the second part. This method is called pulse amplitude multiplexing (PAM); for example, it was used in the Dimension line of PBX's by AT&T.

To make the analog samples digital, they are discretized to the closest of a number n of amplitudes. The number n is usually of the form 2^k with k (in bits) $= 8$ ($n = 256$) for telephone voice, and $k = 16$ ($n = 65\,536$) for CDs. Other values are used for specialized applications. This process is *not* reversible. The error resulting from the irreversibility of the process is called discretization noise.

Thus, the standard process for voice PCM is to assume (conservatively) that $W = 4000$ Hz, and to sample at 8000 samples per second. Then discretizing to 65 536 levels (8 bits) results in a digital signal of 64 000 bps. (Sometimes the least significant bit of the amplitude discretization is "stolen" for use in sending control information. In this case, the data rate is effectively 56 000 bps.) Other discretization methods can be used that take advantage of the fact that the differences between amplitude samples are usually less than the values of the sample themselves. Such methods, called differential encodings, can be used to carry a telephone voice message at 32 000 bps, easily, and with some loss of quality at 16 000 bps.

2.3 Digital Encoding of Digital Data

It would seem in this case that we would simply send the information down the channel. For example, one could simply use one nonzero voltage on a line to represent a binary 1 and another nonzero voltage to represent binary 0. This method is called *non-return-to-zero-level* (NRZ-L). This method is rarely used beyond a few feet; it has significant practical problems. The most significant is that it is difficult to synchronize the decoder with the encoder; that is, it is difficult for the receiver to determine when a bit begins in the signal. In most signaling systems the synchronization between sender and receiver is derived from the signal itself. If a long sequence of all ones or all zeros is sent, one can easily see that deriving the synchronization information is difficult. Moreover, when long sequences of ones or zeros are sent, the signal can have a significant dc component, which is often undesirable.

These problems can be alleviated by using a *biphase method* where a transition is forced each bit time so that synchronization information is always available. Two common biphase methods, used, for example, in local-area networks, are *Manchester* and *Differential Manchester.* Each bit time has average 0, so there is no dc component; there is also always a voltage transition each bit time, to aid synchronization. In the Manchester code a zero is recognized by, say, a transition from high to low in the middle of the bit, while a transition from low to high indicates a binary one. In the Differential Manchester scheme the middle transition has no meaning; it only provides synchronization. The code is whether the signal level changes at the beginning of the bit time or not. For example, a zero could be represented by a transition; a one, by no transition. Note that this scheme is insensitive to polarity of the signal, which is a convenience. Both these schemes have the disadvantage that their fundamental frequency is doubled, which makes the biphase more expensive in bandwidth.

2.4 Analog Encoding of Analog Information

Analog information can be directly carried on a wire without conversion. For example, a voice signal on the telephone local loop is commonly carried at "baseband." Nevertheless, it is common to use an analog signal to modulate a carrier, as in sending digital information on analog lines. There are two main reasons for this.

It is often difficult to send baseband. For example, voice communication uses the frequencies range from about 30 to 15 000 Hz; to send these frequencies directly would require antennas many miles in dimension. Similarly, optical fibers operate at frequencies approaching 10^{14} Hz, which will not support direct transmission of the frequencies of most communication traffic. In addition, the frequency bandwidth associated with the information source could only be used once for one communication. Modulation onto carriers allows many communications to be transmitted simultaneously using different carrier frequencies (frequency-division multiplexing).

The signal can be superimposed on the carrier sine wave by varying one of three defining parameters of the carrier: the amplitude, the frequency, or the phase. These three schemes are called *amplitude modulation* (AM), *frequency modulation* (FM), and *phase modulation.* For analog information, frequency modulation and phase modulation are essentially indistinguishable, and so usually only AM and FM are considered.

3. EFFICIENT USE OF CHANNELS

Even with the immense channel capacities possible with modern fiber-optic communications, it is necessary to make efficient use of channels. The most straightforward way is to multiplex several signals requiring relatively small amounts of capacity onto one larger-capacity channel that has enough capacity to carry all the signals. Often the multiple signals that are carried on a shared channel have characteristics that make greater efficiencies possible. If the signals are bursty, then concentration can be used. Here the shared channel may have a capacity that is less than the sum of the *peak* capacities of the subchannel signals. Of course, the sum of the *average* rates must be less than the channel capacity. The hope is that since the traffics are bursty they will not all be at their peak rates at the same time. Finally, if there is significant redundancy in the information being sent, compression can be used.

3.1 Multiplexing

In multiplexing, the channel capacity of the shared channel is divided among the subchannels. This can be done in three basic ways: by frequency, by time, or by space. In addition, "code division" can be considered to be a multiplexing scheme, although we will consider this as a form of concentration. Multiplexing is an actual partition of the shared channel's capacity. Even if there is no traffic for one or more subchannels, the capacity is still allocated.

The simplest method of multiplexing is to divide the bandwidth of the channel into subchannels by frequency (*frequency-division multiplexing,* FDM). If a transmitted signal is band limited and thus occupies a finite spectral region, other signals can be transmitted at the same time, provided that their frequencies do not overlap. Since frequencies can be shifted at will by means of modulation (or mixing), signals that occupy the same spectral region can be shifted in frequency relative to each other so that their spectra do not overlap. They thus can be added and transmitted over a single communication link. This is frequency-division multiplexing. Demultiplexing is achieved by filtering out the individual signals and shifting them back to their original spectral location. Common examples of FDM include over-the-air television, and AM and FM radio stations. In each case, the stations share a common spectrum (bandwidth), and each is allocated a carrier frequency and bandwidth. For U.S. analog television, the bandwidth allocation for a channel is 6 MHz. Frequency-division multiplexing is the simplest to accomplish since much of it is done by filters that can be passive. However, the filters are not ideal, and extra frequency allotments have to be assigned between channels (*guardbands*) to prevent the signal from one channel escaping into the bandwidth of an adjacent channel. This makes FDM relatively inefficient.

In optical communication, the information-carrying electrical signal modulates the power of the optical source, a laser diode or light-emitting diode (LED). We must thus differentiate between the frequency of the information-carrying electrical signal and the frequency of the optical source, which carries no information. Generally, "frequency" implies electrical signal frequency, whereas "wavelength" refers to the optical source.

Silica-based optical fibers have a transmission window that extends in wavelength between approximately 800 and 1600 nm. This corresponds to a spectral region of 800 nm (or 187 500 GHz). Commercially available laser diodes have a spectral width in the order of 0.1 to 2 nm (or 12.5 to 400 GHz).

A multiplicity of optical sources, adequately separated in wavelength, can thus be coupled to a single transmitting fiber, each source being modulated by different electrical signals and transmitting information independent of each other. This form of FDM (in which the individual carrier frequency sources are uncorrelated to each other) is known as wavelength-division multiplexing, or WDM. Of course, WDM does not preclude the additional use of either frequency division or time-division multiplexing to allow simultaneous transmission of a multiplicity of signals through the individual optical sources.

As the demand for channel capacity increases, WDM will be used extensively in long- and short-haul optical communications. It essentially converts a single fiber into the equivalent of a multiplicity of fibers and allows for network expansion without any major physical modifications of the existing links. It is also envisioned that WDM, in conjunction with photonic switching, will be used to provide to the house and office an assortment of information services, such as voice, video, computer data, and telemetry.

A scheme more efficient than FDM, when it can be utilized, is *time-division multiplexing,* TDM, where the subchannels are separated by time on a digital main channel. Thus, in the simplest case if there are, say, three signals, A, B, and C, one can send a bit from A, then a bit from B, then a bit from C, then a bit from A, . . . on the main channel to derive three equal-capacity subchannels. At the receiving end, a commutator is required to sort out the various signals. Clearly, for proper sorting or demultiplexing of the individual messages, the controlling clock at the receiving end must be synchronized with the clocks of the transmitters. This usually requires that all transmitters feeding the channel are nearly synchronized with each other. Most digital links that use TDM require such synchronization. The overhead for this process is minimal and, therefore, the efficiency high in the sense that the sum of the capacities of the subchannels can be essentially equal to the capacity of the main channel. However, this scheme, like all multiplexing schemes, wastes channel capacity if one or more of the subchannels has no information to send, since the capacity for the subchannel is reserved nevertheless. This scheme is also called synchronous multiplexing since the subchannels do not need to be addressed in any way to be identified but can be identified simply by counting, assuming the receiver and transmitter are synchronized.

Space-division multiplexing refers to the use of physical separation to distinguish subchannels. Examples include

1. wire cables that consist of many wire pairs;
2. frequency reuse in cellular telephony, where a frequency used in one cell can be reused for an entirely different call in another cell sufficiently distant so that the signals do not interfere;
3. the use of separate microwave dishes on the same towers to provide separate channels between the towers; and
4. the use of spot antennas for satellite communications to allow the carriers to be used in different places of the earth to carry different information.

3.2 Concentration, Statistical Multiplexing

Concentration is an extension of TDM. If the traffics to be carried on the subchannels are bursty, then one can rely on the statistical properties of the traffic to assume that, in general, the total amount of traffic summed over the traffics will be substantially less than the sum of the peak traffic rates. This leaves open the possibility of using a main channel with capacity substantially less than the sum of the *peak* rates of the subchannels (although, of course, not less than the total of the *average* traffics). Then one only sends the traffic on the subchannels when the traffic is offered. This approach has several consequences. First, since the traffic to the subchannels varies, one needs an *addressing scheme* so that the transmitter can tell the receiver where in the data stream to find the information for each subchannel that is active. For this reason, the subchannels cannot be identified simply by having a synchronized clock as was the case with TDM. Because of this, concentration is also called *asynchronous multiplexing.* Another very common term for this approach is *statistical multiplexing,* reflecting the dependence on the statistical properties of the traffic on the subchannels. A second consequence of concentration results from the fact that while in the long run there is enough capacity on the shared channel to support the subchannels, on occasion, hopefully rare, the total of the subchannel rates will exceed the shared channel rate for short periods of time. This is handled by providing *buffering* to store the excess traffic until the transmitting subchannels reduce their load on the system and the saved traffic can be metered out. This can give rise to two kinds of problems. First, the buffer may become filled up and data lost (in practice, signals are often sent back to the transmitters using the subchannels, inhibiting them from further transmission until the buffer clears). Second, the buffering can introduce substantial and varying delays (jitter). These latter problems are particularly onerous for real-time applications.

There is still another way of concentration that allows multiple digital users to share the same channel. This is code-division multiplexing (CDM). CDM is based on the rather counterintuitive notion of increasing the natural bandwidth, B_0, of each user to a larger one, B; that is, we spread the spectrum. This technique of spread spectrum arose out of military efforts to combat jamming and to provide secrecy. The ratio of B to B_0 is called the *spreading factor.* All users share the same time and the same spectral interval but use a different spectrum spreading code. This can be done in one of two ways (or both). Each bit can be translated in time into a coded sequence of B/B_0 digital signals called *chips.* Such spreading codes are called *direct sequence* codes. Alternatively, the signal can jump from carrier frequency to carrier frequency in time. These are called *frequency hopping* codes. A replica or replicas of the spreading codes are available at the receiving end. Correlation or other techniques are used that result in collapse of the spectrum and recovery of the signal. The spreading factors, whether direct or frequency hopping, are designed so that received signals that do not correspond to the desired signal when correlated with the replica of the desired signal results in a collapsed signal that is near zero and appears as low-level noise superimposed on the desired signal. This allows the desired signal to be recovered from the shared spread spectrum even in the presence of other communications in the same spectrum.

While CDM requires more bandwidth than either FDM or TDM, it often results in more efficient frequency utilization because a transmitter only uses bandwidth when it is active. This approach is especially useful in satellite and cellular radio communication links.

3.3 Compression, Error Control, and Encryption

Suppose we consider n bits of information from the same information source at various intervals of time. We can think of these n-bit strings as random variables with distribution determined by the source. If all possible 2^n n-bit strings are not equally likely, then the source has *redundancy* and the messages can be coded in such a way as to reduce the required data rate. Redundancy plays a key role in three areas of communications.

1. Compression: To the extent that "messages" are redundant they can be compressed to take up less communication or storage capacity.
2. Error detection and correction: One can add redundancy of a "good" sort to make it possible to detect or even correct transmission errors.
3. Cryptography: Redundancy is essential for breaking codes when all you have available is ciphertext (encoded messages). Conversely, the objective of encryption is to make the ciphertext appear as random as possible to minimize the redundancy.

Redundancy "measures, in a sense, how much text in the language can be reduced in length without losing any information" (Shannon, 1949). A little more precisely, a language is redundant if for some n, not all strings of length n have the same probability. Redundancy also measures the structure of a language, message, or source. Language structure limits the number of strings or their likelihood so that not all strings are equally likely. For example, in English, "q" is normally followed by "u," and "t" is frequently followed by "h."

3.3.1 Compression A simple, but frequently used, example of compression is *run-length coding.* For example, when sending a facsimile of a page with a lot of white space, long sequences of white pixels will appear. This can be much compressed by making use of a special code (escape character) followed by the character (pixel in this case) that is repeated, followed by a count of the number of repeats. At the received end the original bit map can be exactly recreated by replacing the code, the character, and the count by the appropriate number of characters. In general, there are two types of compression, *reversible* or *lossless* and *irreversible* or *lossy* compression. Run-length coding is an example of the first type because the exact signal before compression can be precisely reconstructed at decompression. For voice, image, and video applications, the compression ratios, ranging up to about 10:1, obtained by lossless compression are often not sufficient. Higher compression ratios, up to about 100:1, can be achieved at the cost of some loss in accuracy of the decompressed message compared to the original one. These inaccuracies are carefully controlled so as to not degrade the received message too much in the context of the application it is used for. However, for some applications, particularly for data services, only lossless compression will do.

3.3.1.1 Lossless Compression. After run-length coding, the two most commonly encountered lossless compression schemes are Huffman coding (Huffman, 1952), and Lempel–Ziv coding (Ziv and Lempel, 1978).

The latter approach, in particular, is used commonly for compressing computer files for storage and transmission. Huffman coding is a generalization of the Morse code. When Morse constructed his telegraph code of dots, dashes, and spaces, the codes for different letters were, in general, of different length. He was careful to assign the shortest codes, for example e = *dot* and t = *dash,* to common letters and long codes, e.g., j = *dot dash dash dash* and q = *dash dash dot dash* for less frequent letters. This gives compression because of the more frequent occurrence of short letters in common text. Note that this gain is lost if there is no redundancy in the original text; if each letter is equally likely, compression gain cannot be achieved in this way. Huffman coding is an optimal scheme in the following sense. We assume that we are transmitting messages expressed in an "alphabet," say the 7-bit ASCII character set, and that we know the frequency of occurrence of the various characters in the alphabet; that the frequency is stable in time; and that the characters are generated with these frequencies independently of one another. Unfortunately, the last assumption is blatantly false, and the others are difficult to achieve in practice. Nevertheless, Huffman provided an algorithm for assigning variable–bit-length codes for the characters so that the average expected message lengths would be minimal over such codes. Lempel and Ziv introduced a coding scheme that is adaptive. It learns the statistical properties of the source "on the fly," and it adapts to changes in these properties as well. In their system the encoded elements are of constant length, but the source text that they represent is variable; Huffman coding is exactly the other way around.

3.3.1.2 Lossy Compression. For many applications, particularly multimedia ones, the compression ratios achievable by lossless compression do not suffice. Two schemes commonly used for achieving higher ratios at the cost of some inaccuracies in the decompressed message were developed by the Joint Photographic Experts Group (JPEG) and the Moving Picture Experts Group (MPEG) of the International Standards Organization. Both methods treat images in a similar way. We sketch the JPEG scheme. It takes place in three steps. In the first step the image is divided into 8-pixel by 8-pixel blocks. The blocks are then individually converted into the "frequency" domain by a discrete cosine transformation (DCT). This is motivated by the fact that the higher-frequency elements of the block are usually less important for human perception than the lower ones. In the second step the DCT coefficients are discretized. Compression is achieved by discretizing the coefficients corresponding to higher frequencies more grossly. The amount that this is done is controlled by a quality parameter. The higher the parameter, the more compression and the less the fidelity of the reconstructed image. After the second step, many of the coefficients, especially those corresponding to high-frequency terms, will be zero. A form of run-length coding of zero coefficients plus either Huffman coding or arithmetic coding provides final compression. Note that only the second step introduces loss. The first and third steps are lossless (reversible).

MPEG uses these devices plus additional ones to take advantage of the correlation in time of successive images in movies and videos.

3.3.1.3 Uses of Compression in Telecommunications. Despite the seemingly unbounded bandwidth of fiber-optic channels, compression still plays a very important role in many aspects of modern telecommunication. Lossless compression is used to reduce the storage and communication capacity for data communications. Compression ratios near 10:1 are routinely obtained for facsimile transmission. Modern high-performance modems use a form of Lempel–Ziv coding to improve data rates. Lossy compression is used in many multimedia applications. To transmit full-motion video from CD-ROMs, over telephone or CATV channels (e.g., video on demand), or over satellite channels, lossy compression is virtually always used.

3.3.2 Error Detection and Correction

All communication channels and networks have errors due to noise and other factors. If special techniques are not used, these errors often are more frequent than the application can tolerate. Thus, one would like to correct errors as they are received or detect their existence and, if necessary, retransmit them. This can be done by adding redundancy to the messages. Thus, on the same channel one can be using compression techniques to reduce the required transmission and adding redundancy to detect and/or correct errors. To illustrate the ideas involved with the detection and correction of errors, we introduce a simple but inefficient method. Suppose we are attempting to transmit a message of n bits over a channel that is subject to transmission errors. One coding is to simply send the message more than once. For example, suppose we send the message twice. We then compare the two received messages bit by bit, and for those corresponding bits that do not match, we declare an error; otherwise, we say that the common value of the bits is the true value. There are at least three significant drawbacks to the scheme. First, on occasion, both of the corresponding bits could be wrong, in which case we would declare the wrong value correct. This problem can be particularly acute if the probability of a bit being in error is high or if the size of the message n is large. Second, while we can detect errors, we cannot correct them using this technique. Third, we are rather wasteful of communication resources since the effective length of each message is doubled. The first two problems can be eased at the cost of worsening the third by sending more than two copies. For example, we can send three copies of the message. Then we say a given bit of the message is received correctly if the corresponding bit of each of the three copies has the same value. We can correct a bit, if there are discrepancies by taking the bit value that appears at least twice in the three copies. If we wish more confidence, we can send even more copies. However, this is very inefficient. Fortunately, there are very much more efficient methods. Two common methods are *parity check* bits and *cyclic redundancy checksums* (CRCs). Parity checks are a rather weak form of error detection but appear commonly. The idea is that, given a sequence of bits from a message, typically 7 bits, redundancy in the form of an additional parity bit is added so that the total number of ones in the eight bits (byte or octet) is even in the case of *even parity* or odd in the case of *odd parity*. The overhead of this type of coding is 1/7 or about 14.3%. CRCs are much more effective. Typically, a message of 8 000 to 16 000 bits has added to it a checksum of 32 bits. The overhead here is then less than 1%, and the protection is strong. The general idea of the CRC is that we interpret the bits of a message M as a binary "number." Associated with a given redundancy system is a generator, G, which is also interpreted as a binary number. Typically, G has much fewer bits than M. Then one divides M by G, obtaining a remainder R, which will be smaller than G. Essentially, the message M is transmitted along with the remainder R. The receiver, who also knows the generator, then takes the received message M' and the received remainder R' and recomputes the remainder of M' when divided by G, to obtain R''. If $R' = R''$, the message is deemed correct. To make the process more efficient, the process is not exactly as described here. For example, in practical implementations M and G are not actually interpreted as ordinary numbers but rather as elements of a field over the integers modulo two. Moreover, things are arranged so that the receiver, instead of comparing two strings, compares a processed part of the received string with a string of zeros of the same length. For smart choices of G, most common errors can be detected and many corrected. In practice, if the remainder checks out okay, the receiving party sends an acknowledgment to the sender. If the sender does not receive an acknowledgment, it sends the message again. In some applications—for example, in communication with deep-space probes—this retransmission process is much too inefficient because of the long propagation delays. In these cases, forward error correction is more useful. Here, additional redundancy is added so that the errors can actually be corrected with very high confidence without retransmission. Similar techniques are used on CD-ROMs, so that minor imperfections in the discs can be corrected for.

3.3.3 Encryption For many applications, secrecy of communications is important. This is often provided by encryption. There are many other applications as well. For example, one often needs to authenticate the other party in a communication to provide confidence that one is communicating with the appropriate party or that the entity making use of computing or communication resources is entitled to do so. There are two basic types of encryption systems in use. The first type is variously called *symmetric, pri-*

vate key, or *single key.* The other approach is called *asymmetric, public key,* or *two key.* If Alice wishes to communicate a message *M* to Bob using the first system, they must share a common secret key *K*. Alice then encrypts *M* using *K* to obtain ciphertext, *C*, using an encryption algorithm. The algorithm must have the property that is very, very difficult to recover the *M* from *C* unless *K* is known. If *K* is known, then one can simply recover *M* from *C* using a decryption algorithm. The Data Encryption Standard (DES) is a commonly used example of a symmetric key system. In asymmetric systems, two keys are used. Alice encrypts *M* using a public key, which is well known to belong to Bob, obtaining ciphertext *C*. Bob then recovers *M* from *C* using a different private key that no one else knows. A common example of an asymmetric cryptography is the Rivest–Shamir–Adleman (RSA) algorithm (Rivest *et al.,* 1978). In general, symmetric systems such as DES can be implemented to run much faster than asymmetric systems such as RSA. On the other hand, asymmetric methods are more flexible and can be used for more applications. Quite often, hybrid systems using both types of encryption are used where the asymmetric method is used to establish the secret key for use by the more efficient symmetric algorithm.

4. EFFICIENT USE OF NETWORKS

4.1 Circuit, Message, and Packet Switching

In Sec. 3, we discussed the efficient use of individual telecommunications channels. Similar considerations obtain in networks of channels. We will think of a communication network as consisting of terminals, switches, and channels. The terminals originate or terminate traffic, the switches route information, and the channels carry the traffic between terminals and switches.

There are two basic ways that a network of channels can be used for communication. In the first way, *circuit switching,* logically a string of channels are hooked together at switches to form a path from the sender to the receiver. While communication is active, the entire path is dedicated to the communication. This use of networks has the advantage that the message is not delayed as it travels through the network. It simply sees what looks like a single channel derived from the network. It generalizes the notion of multiplexing for channels to networks. Moreover, like multiplexing, no addressing is needed to identify or route the traffic after the call is set up. This use of a network is most useful for traffics that are smooth, or for real-time traffic such as voice or video. Like multiplexing, in circuit switching the channel is dedicated so that when it is not being actively used the capacity is wasted and not available to others.

At the other extreme is *message switching.* Again the message works its way through the network. However, it does so only one switch at a time. In message switching, each channel is used only while the message is traversing it. The message is thus sent from the origin to the first switch. The message is then stored in that switch. Then the message is passed to the next switch. The channel from the origin to the first switch is no longer involved with the transmission. This procedure is continued until the message reaches the destination. This technique is related to statistical multiplexing where the channels are only used when there is traffic to be sent. However, latency or delay is encountered at each switch, since the message has to be read into the switch and then retransmitted. The longer the message, the longer the delay *at each switch.* To control this delay, *packet switching* was introduced in the late 1960s, where each message is broken into packets with a fixed maximum length. Thus since no packet can be larger than a given size, the retransmission delay at each switch is limited. In recent years this approach has been extended in asynchronous transfer mode (ATM) to where all communication takes place in cells that all have the same short (53 octet) length. In general, different packets between a given origin and destination need not follow the same path through the network. This makes addressing necessary to identify the packets and to route them. Packet switching is most useful for bursty traffic so that the statistical variations can be taken advantage of. An intermediate approach is the *virtual circuit.* In this case, the information is broken into packets, but the packets all take the same path through the network. However, in general, the path is not dedicated to the virtual circuit, and other traffics can use the channels in the path on occasion. This, for example, reduces the addressing requirements while still allowing the communications capacity to be dynamically shared.

4.2 Architectures, Standards, and Protocols

As telecommunications systems become more complex, agreements are being forged that help to organize the hardware and software components effectively. One useful way to organize one's view of the software and hardware of a communication network is according to the Open Systems Interconnection Model of the International Standards Organization. The functions of communication are partitioned, hierarchically, into seven layers. They are

1. the Physical layer,
2. the Data Link layer,
3. the Network layer,
4. the Transport layer,
5. the Session layer,
6. the Presentation layer, and
7. the Application layer.

These layers correspond to different views of the network. Layers 1 and 2 are only concerned with individual links within the network. Layer 3 actually deals with the way the information travels *through* the network, while the higher levels, levels 4–6, have the "cloud view" of the network. They only see information entering and leaving the network, but the workings within the network and its individual channels are hidden from these higher levels. In the early 1970s Vint Cerf and Bob Kahn (Cerf and Kahn, 1974) developed the theory of internetworking, which gave rise to the TCP/IP model of communication and, ultimately, the Internet.

5. TRANSMISSION MEDIA

Transmission media can be divided into two categories: wireless transmission into air or space and transmission into constrained channels such as wires or cables.

5.1 Wireless

For many reasons "tetherless" communication is desirable, that is, communication where the communicating entities do not have to be connected by wires or cables. For example, if one or both ends of a conversation are in motion, wire or cable connections are often impracticable. Likewise, great distance or difficult terrain may make wire connection infeasible. Finally, the broadcast nature of wireless communication supports the convenient transmission of the same information to many receivers. This is useful for radio and television. Because the environment is less controlled, wireless transmission is more difficult than using cables or wires. However, if the antennas for wireless communication are fixed and can be well situated, the performance can be quite predictably good. This is the case for satellite communication to fixed ground stations and point-to-point microwave communication between fixed antennas. The performance is limited mainly by the free-space loss inherent in any signal radiated into space or the atmosphere, by atmospheric absorption, and by refraction. On the other hand, mobile communication or communication with antennas that cannot be located for best transmission is much more complex. Fading, multipath interference, and a number of other additional performance degradations occur.

Cordless telephones, mobile telephones, and even phones in airplanes are examples of modern wireless communications. Paging and messaging services are other examples.

5.1.1 Limitations on Wireless Communications

5.1.1.1 Free-Space Loss. For any wireless communication, by the geometry of the radiation, the signal diverges with distance, decreasing the signal intensity. For satellite communication this is the primary mode of "attenuation." Under idealized conditions, the ratio of the power P_r received by the antenna to the radiated power P_t is given by $P_r/P_t = A_rA_t/(d\lambda)^2 = A_rA_tf^2/(cd)^2$, where A_r is the effective area of the receiving antenna, A_t is the effective area of the transmitting antenna, d is the distance between the antennas, f is the carrier frequency, $\lambda = f/c$ is the wavelength, and $c = 300\,000$ km/s is the speed of the electromagnetic wave. Thus, for the same antenna dimensions and separation, the higher the carrier frequency f, the lower is the free-space path loss, which is the fraction of the loss that depends only on the divergence with distance and not on the antennas. However, the ration P_r/P_t is most commonly expressed in a different form. With $G_r = 4\pi A_r/\lambda^2$ and $G_t = 4\pi A_t/\lambda^2$ being the "gains" of the receiving and transmitting antennas (relative to isotropically radiating antennas), respectively, $P_r/P_t = G_rG_t(\lambda/4\pi d)^2 = G_rG_t(c/4\pi df)^2$, giving a "free-space path loss" = [32.4 + 20 log(d/km) + 20 log(f/GHz)] dB. This seems to imply, erroneously, that the path loss increases with the square of carrier frequency if one loses sight of the dependence of antenna gain on frequency.

5.1.1.2 Absorption. An additional loss between the transmitting and receiving antennas is absorption. Two atmospheric gases contribute most to attenuation: water vapor and oxygen. A peak of approximately 0.2 dB/km for an absolute humidity of 15 g/m^3 occurs in the vicinity of 22 GHz due to water vapor. At frequencies below 15 GHz, the attenuation is reduced to less than 0.04 dB/km. The presence of oxygen results in an absorption peak of 10 dB/km in the vicinity of 60 GHz but contributes less than 0.02 dB/km at frequencies below 30 GHz. Accordingly, at frequencies below 15 GHz, typical path lengths of up to 50 km are essentially unaffected by atmospheric absorption.

Rain and fog (suspended water droplets) cause scattering of radio waves that results in attenuation. This can be a major cause of signal loss. The degree of attenuation depends on the rainfall rate and frequency. Light rain (1 mm/h rainfall rate) will cause attenuation of 0.05 dB/km at 10 GHz and 0.3 dB/km at 20 GHz; when the rain is heavy (15 mm/h), the respective attenuation values are 0.7 and 3.0 dB/km; cloudburst rain (100 mm/h) causes attenuation of 5 and 25 dB/km at 10 and 20 GHz, respectively. Neither space diversity nor frequency diversity are effective as protection against rainfall effects. Thus, in areas that experience significant amounts of precipitation, either path lengths have to be kept shorter or lower-frequency bands should be used.

5.1.1.3 Multipath. When an obstacle is below the line-of-sight path, the divergent radio wave can be partially reflected to form a second signal at the receiving antenna. At the point of reflection, the indirect signal undergoes attenuation and is shifted in phase by approximately 180°. The reflected signal can be particularly strong when the reflecting surface is water or smooth terrain. At the receiving antenna, the direct and reflected signals combine. Depending on the differences in the path lengths of the direct and reflected waves, the composite signal can be either larger or smaller than the direct signal. Reinforcement and cancellation of the signal resulting from the signal following multiple paths can be controlled for communication between fixed, well-sited antennas and between satellites and fixed ground stations, but for mobile telephony and communication to antennas that are not well sited, multipath considerations can be paramount, and no direct path may in fact exist.

5.1.1.4 Refraction. Additionally, radio waves are refracted (or bent) when they propagate through the atmosphere. The refraction is caused by changes in the dielectric constant or refractive index with altitude, or by other spatial changes in the atmospheric conditions. Normally, the refractive index decreases with altitude, causing radio waves to diffract downward. However, on occasion, weather conditions may lead to refractive index variations with height that differ significantly from the typical variations. This may result in a situation in which only a fraction or no part of the line-of-sight wave reaches the receiving antenna. When the refractive index variation is more rapid, anomalous wave propagation or "ducting" may occur. The result is attenuation of the line-of-sight signal and/or frequency-dependent changes in the interference between the multipath signals. In either case, the signal fades. This fading is usually of short duration. Both space diversity and frequency diversity are helpful in combating fading.

5.1.1.5 Thermal Noise. Thermal or "white" noise is inescapable. It arises from the thermal activity of the devices and media of the communication system. Because of the weakness of the signal received by satellite Earth stations, thermal noise is particularly important for satellite communication.

5.1.2 Satellite Communication Satellite transmission is unique in that it is capable of providing global communication, including transmission to and from moving terminals (such as trucks, ships, and airplanes), without the need of an extensive terrestrial infrastructure.

Geosynchronous satellites remain in a fixed position in the sky relative to the earth. For this to be the case, the satellite must be in the equatorial plane, and its circular orbit must have a period of one day, identical with that of the Earth's rotation. This requires an altitude of 35 838 km. From such an altitude, four satellites can cover most of the planet's surface. Only the polar regions, beyond 81° latitude, remain beyond the line of sight of geosynchronous satellites. This configuration has many advantages to recommend it. Because the satellite is stationary relative to the Earth, there is no problem with frequency changes due to relative motion of the satellite and earthbound antennas. Moreover, the tracking of the satellite by its Earth stations is simplified. On the other hand, there are some problems. The most obvious one is that the signal can get quite weak after traveling at least 35 838 km. Also, the polar regions and the far northern and southern hemispheres are poorly served by geosynchronous satellites. Moreover, even for signals traveling at the speed of light, 300 000 km/s, the delay in sending a signal to the satellite and back is considerable.

The distance from an Earth station to a geosynchronous satellite may range from a minimum of 35 800 km to a station on the equator beneath the satellite to 41 800 km for a station at the horizon relative to the satellite. Accordingly, the one-way propagation time from one Earth station to another may be as long as 280 ms, resulting in a round-trip delay time of 560 ms. In conversational voice communication this is acceptable. However, often a domestic satellite is used in tandem with an international satellite. In such a case the total trip delay is over 1 s, which might not be tolerable. For such reason, international satellite transmission is often implemented on a one-way basis, with the return path being terrestrial, such as an optical-fiber submarine link.

Geosynchronous satellites use their assigned frequencies over a very large area, although the area can be restricted to some extent by using special antennas on the satellite such as spot and steered beam antennas. For some broadcasting applications this is an advantage; however, it does limit the reuse of the satellite frequencies. To solve these problems, orbits other than geosynchronous have been designed for satellites. Two of importance are highly elliptic orbits and low Earth orbits (including space stations).

In northern Europe and in polar regions the angle of geosynchronous satellites above the horizon can be uncomfortably low. At low angles, satellite signals are easily obstructed by natural obstacles, hills and mountains, and by man-made ones, buildings. In northern Russia this is a particularly pronounced problem. To deal with it the Russians have used highly elliptic orbits for some of their satellites. The prototype of this type of orbit was used by the Russians in the Molniya series of satellites. The Molniya orbit was designed to offer a better angle of inclination of the satellite to the horizon in the far northern hemisphere and the polar region. The orbit is elliptical and is inclined 65° with respect to the equator. It is at its farthest from the Earth at the 40 000-km (slightly more than the 35 838-km height of a geosynchronous satellite) apogee over the northern hemisphere, and is closest, 500 km, at its perigee in the southern hemisphere. Thus it has very good coverage over the northern hemisphere. Moreover, the satellite spends most of its 12-h orbit over the northern hemisphere. Three satellites sufficed for 24-h coverage. A similar system was proposed by the European Space Agency for digital audio broadcasting.

This type of satellite has little to recommend it beyond its coverage of polar regions. Because the orbit is not geosynchronous, multiple satellites are needed for 24-h coverage. Moreover, to the extent that the apogee is greater than geosynchronous orbit altitude, the signal attenuation (loss) is even more.

The original AT&T satellite proposal was for low Earth-orbiting satellites (LEOs). However, most of the early satellites were geosynchronous. Nevertheless, low Earth orbits have advantages, and many recent satellite proposals (e.g., Motorola's Iridium) are based on them. The idea is to use constellations of low Earth-orbiting, inexpensive satellites sometimes called "lightsats." They orbit at altitudes of about 750–3000 km above the Earth's surface. Therefore, their signal is much stronger for given transmission power than geosynchronous satellites. Their coverage can be better localized so that spectrum can be conserved. For this reason, this technology is being currently proposed for communicating with mobile terminals and personal terminals, which need stronger signals to function. On the other hand, to provide broad coverage over 24 h, many satellites are needed. Sixty-six are being proposed by Motorola for their Iridium system.

A number of commercial proposals have been made to use clusters of LEOs to provide communications services. These proposals can be divided into those intended to work at communication frequencies less than 1 GHz and using no more than 5 MHz bandwidth and supporting data rates up to 10 kbps, the "little LEO's," and those working at frequencies above 1 GHz and supporting data rates up to a few megabits per second, the "big LEO's." LEO systems operating below 1 GHz typically are aimed at paging, tracking, and low-rate messaging applications. Big LEO systems tend to offer the same services as small LEO systems with the addition of voice and positioning services. The Iridium system is planned to be a big LEO.

The first satellite to use active repeaters was launched in 1962. These early satellites were placed in low orbits and required complex Earth stations to track the motion of the satellite. The first commercial geosynchronous satellite was placed in operation in 1965. By 1970, the international satellite consortium INTELSAT had established a global satellite-based telecommunications network.

The lifetime of a geosynchronous satellite is typically 10 to 20 years, while LEOs are designed for a 7- to 10-year life. The life of a geosynchronous satellite is limited by the amount of propellant stored onboard for firing thrusters that keep the satellite to within 0.5° of its assigned position.

The transmitted satellite power is orders of magnitude greater than power received by its antenna. To affect isolation between the transmitted and received signals, the received signal is shifted in frequency for retransmission. For a number of reasons, the lower frequency is assigned to the downlink.

The most desired frequencies for commercial use are in the 4- to 6-GHz band. The downlink is 3700 to 4200 MHz, and the uplink is 5925 to 6435 MHz. This frequency band is suitable for use under all possible weather conditions. Moreover, in this frequency range the equipment is relatively inexpensive, and the cosmic noise is small. However, since existing terrestrial microwave radio links operate in the 4- to 6-GHz bands, the FCC limits the power density on Earth from satellite transmitters (to 12 dbW effective isotropically radiated power in any 4 kHz band).

In a typical satellite, the 500-MHz bandwidth is subdivided into twelve 36-MHz bands, with 4.0-MHz guardband separation. Each of the 12 transponders aboard the satellite amplifies the signal received from the uplink and down-converts it by 2225 MHz for transmission on the downlink. Some satellites use polarization diversity to reuse the same frequency band. Such satellites have two sets of 12 transponders that operate with orthogonally polarized signals.

An antenna beamwidth of 17.3° would cover the entire surface of the Earth that is within view of the satellite. Within a factor of 1 to 2, the beamwidth of an antenna equals the ratio of the carrier wavelength to the antenna dimension. Thus, in the 4- to 6-GHz band, maximum coverage would be provided with an antenna 25 cm in diameter. However, satellite antenna dimensions are significantly larger than 25 cm, and, correspondingly, the beamwidths are much smaller. For one reason, the signal power density at the Earth's surface is proportional to the square of the antenna dimensions. Moreover, spot beaming is often used to increase the available bandwidth by allowing the reuse of frequencies in different areas of the Earth. The total available bandwidth is limited by the total number of satellites that can be placed in orbit. The U.S. standard allows synchronous satellites in the 6/4-GHz band to be assigned an orbital spacing of 2°.

Because there are few vacant spectral assignments in the 6/4-GHz band, newer satellites operate in the *Ku* band. These satellites use 11.7 to 12.2 GHz for the downlink and 14.0 to 14.5 GHz for the uplink. The allowed minimum orbital spacing is 3°. This commercial spectral band is suitable for use under most weather conditions. The bands above 17 GHz are more severely limited by precipitation.

Satellites are now used extensively to relay broadcast-quality television signals. Typically, a single 36-MHz transponder is used for each TV signal. This is accomplished by modulating the composite video and audio signals to generate an FM signal of 36-MHz bandwidth.

Satellite relays provide a channel for telephone and data signaling similar to conventional terrestrial links. Thus, either telephone signals can be frequency-division multiplexed and upconverted in frequency for transmission or the signals can be converted into 64-kbps PCM digital signal that are time-division multiplexed and modulated into a carrier for transmission. Correspondingly, either data can be time-division multiplexed or modems may be used to convert the data into signals that are compatible with analog transmission and FDM. Depending on the mode of transmission, three main methods are used to provide multiple access:

1. frequency-division multiple access (FDMA),
2. time-division multiple access (TDMA), or
3. code-division multiple access (CDMA) or other variants of spread-spectrum multiple access.

In all methods, the multiple access assignment can be either fixed (FAMA) or demand based (DAMA). In the DAMA mode, the assignment formats are changed in real time as needed to accommodate the traffic demands of the Earth stations involved. Clearly, this mode of operation uses the satellite capacity more efficiently but is more complex to implement than a fixed assignment.

5.1.3 Point-to-Point Wireless Communication Microwave radio systems provide cross-country communication links through the use of multiple repeater sites, as well as feeder service to long-haul coaxial and fiber cable systems. Individual circuit lengths range from a few kilometers to thousands of kilometers. Applications include telephone channels, wide-band data, and television transmission.

Microwave transmission uses line-of-sight free-space propagation of electromagnetic waves. Antennas are placed on towers of sufficient height to provide a direct and unobstructed path between the transmitting and receiving sites. The microwave spectral region extends from about 1.5 to 30 GHz. At these frequencies the predominant mode of signal transmission between the two radio antennas is direct line-of-sight propagation. Other modes of propagation, such as ground or surface waves that parallel the Earth's surface, ground reflection paths, and/or waves reflected off the troposphere or ionosphere, may cause destructive interference with the line-of-sight wave, and the signal will fade. Line-of-sight links are limited in length by the divergence of the electromagnetic wave ("free-space loss"), by obstacles along the path, and by curvature of the Earth. Terrain, atmosphere, and precipitation further affect the link length and signal quality.

Multipath propagation and atmospheric refraction changes cause time-dependent interference effects and result in signal fading.

Digital service constitutes an increasing portion of microwave transmission. Digital coding requires less power than analog signaling and is more immune to fading and other channel degradations. However, since digital modulation techniques result in broadband signals, filters must be used to limit the bandwidth of the modulated signals to the assigned radio channels while still allowing transmission with a minimum of intersymbol interference.

In the United States, radio channel assignments for commercial carriers are controlled by the Federal Communications Commission (FCC). FCC regulations specify the microwave frequency bands that are authorized for digital microwave and establish standards for efficient use of the radio spectrum and the control of interference between adjacent radio channels.

In the 2.11- to 2.13-GHz band, a radio channel bandwidth of 3.5 MHz is allowed with a minimum capacity of 36 PCM 64-kbps voice channels per radio channel. To achieve the required 6.312-Mbps rate, either 8-level phase-shift keying (PSK) or 16-level *quadrature amplitude modulation* (QAM) is typically used. The same radio channel bandwidth and minimum capacity requirements are specified for the 2.16- to 2.18-GHz band. For operation in the 3.7- to 4.2-GHz band, the radio channels are 20 MHz wide, with a minimum capacity of 1152 64-Kbps channels. A commercially available 64-level QAM system achieves the 90-Mbps rate at 15

Mbaud. The 30-MHz radio channel bandwidth available in the 5.925- to 6.425-GHz band allows a yet higher transmission rate if 64-level QAM is used. Three DS-3 streams, or 135 Mbps, corresponding to 2016 voice channels at 64-Kbps each, can be transmitted by such systems. The same or higher transmission rates are possible in the 10.7- to 11.7-GHz band with an allowed radio channel bandwidth of 40 MHz.

The conventional practice in frequency channel assignment for a particular band is to separate transmit and receive frequencies by placing all transmit channels in one half of the band and all return channels in the other half. Within each half-band, adjacent radio channels must be spaced far enough apart to avoid signal interference between channels. A common scheme used to increase adjacent channel discrimination is to alternate between vertical and horizontal polarization of the wave. This cross-polarization of adjacent channels provides isolation of more than 20 dB.

One commercial high-capacity radio-relay system in the 10.7- to 11.7-GHz band has six transmit and six receive radio channels, each having a 40-MHz bandwidth. Adjacent channels are separated by 27 MHz, and the separation between the transmit and receive half-bands is 140-MHz. The bit rate is 135 Mbps, providing 2016 digital voice channels per radio channel, for a total of 12 096 full duplex voice channels. Even higher capacities are possible with more recent systems.

Frequencies beyond the 10.7- to 11.7-GHz band have also been allocated by the FCC. They are, however, not in common use for transmission beyond metropolitan areas because of propagation problems during precipitation.

In the past, microwave radio systems provided over 70% of all the toll-message circuit distance within the United States. However, because of privacy concerns, rights of way and antenna location concerns, and capacity limits (to at most 50 000 full duplex circuits), the economic and engineering importance of analog and digital microwave radio is diminishing in comparison with optical-fiber communication links. Such links are next to impossible to tap, do not radiate, and are noise free, and the capacity of a cable with ten fibers is in excess of one million full duplex digital voice channels.

5.1.4 Mobile Telephony The first generation of mobile telephony was based on analog technology. Initially, conventional radio telephone service was used. Typically, in such a system perhaps only 666 voice channels would be available in a 40-MHz band. Service is provided through a high-power transmitter/receiver with an effective range of approximately 100 km, covering an area of 30 000 km^2. Consequently, when a channel is used by anyone in the area, it is not available for use by others. However, since the early 1980s, this approach has been largely supplanted by cellular systems such as the Advanced Mobile Phone Service (AMPS) developed by AT&T.

The cellular radio concept is to decrease the power of the transmitter and, correspondingly, reduce the range of the system to no more than a few kilometers. Thus, an area is divided into cells, each one served by its own antenna. Many more users can now be accommodated simultaneously, since the same radio-frequency channel can be used by another individual in a cell sufficiently distant. If more channels are needed, the existing cell sizes are decreased so that the existing channels can be reused more efficiently.

In the United States, two 25-MHz bands are allocated to AMPS, one for transmission from the base station to the mobile unit, 869–894 MHz, the other for transmission from the mobile unit to the base station, 824–849 MHz. Each of these bands is split in two to encourage competition; i.e., so that in each market two operators could be accommodated. An operator is allocated only 12.5 MHz in each direction for its system. The channels are spaced 30 KHz apart, which allows a total of 416 channels for an operator. Twenty-one are usually allocated for control, leaving 395 to carry calls. The control channels are data channels operating at 10 kbps. The conversation channels carry the conversations in analog using frequency multiplexing. At present, the telephone signals are frequency modulated with a frequency deviation of 12 kHz and bandwidth of 30 kHz. Frequency-shift keying is used for control signals. Control information is also sent on the conversation channels in bursts as data. Efforts are under way to use different encoding techniques, which will result in better spectral utilization.

No specific channel is assigned to a particular party. When a phone is on the air it automatically transmits its serial number to the Mobile Telephone Switching Office (MTSO). When a call is initiated, the MTSO assigns an available radio channel to the user's cellular phone and sends a ring signal to the called party. If the called party is land based, the connection is made via a central office to the telephone network. If the called party is mobile, the MTSO connects the user to the cell site that covers the area in which the called party is located. Available channels in that cell are used for base-station to mobile and mobile to base-station transmission. As the mobile users travel from one cell to another, the MTSO automatically switches them to available channels in the new cells, and the telephone conversation continues uninterrupted.

Second-generation mobile telephony, also generally based on the cellular concept, uses digital radio, which offers more efficient use of the spectrum as well as more functionality. One such system is the Global System for Mobile (GSM), which is very popular in Europe and is probably the fastest growing mobile telephony technology.

The third generation of mobile telephony will be the integration of mobile telephony into more general universal personal telecommunications and universal communications access. The first of these means the ability of a person to use conveniently any communication system in a large geographical area, perhaps globally, in terms of a single account. For example, one's phone number would travel with the person, not with a particular communication device. The second concept is that of a customer having one portable terminal that will work equally well in the office, on the street, and on airplanes or automobiles. Personal Communications Services (PCS) and Personal Communication Networks (PCN) are names attached to these concepts of global wireless communications.

PCS handsets are designed to be low power, and relatively small and light. Efforts are being made internationally to allow the same terminals to be used worldwide. Frequency allocations, worldwide, have been made for second-generation cordless telephones (CT-2) in the 800-MHz region and for more advanced personal communications (third generation) in the 1.7- to 2.2-GHz region of the spectrum.

The 1992 World Administrative Radio Conference (WARC 92) assigned worldwide allocations for "future public land mobile telecommunications systems (FPLMTS)." This concept includes both terrestrial and satellite-based services.

In addition, allocations were made for low Earth-orbiting (LEO) satellite services that can be used to support personal communications.

Some proposed technologies that come under the umbrella of PCS are American Digital Cellular System, Japanese Digital Cellular System, second-generation cordless telephones (CT-2), the European Community's GSM digital cellular service, and Digital European Cordless Telephone (DECT) for services such as advanced in-building wireless telephony, all supported by LEO satellites, and geosynchronous satellites, as well as terrestrial antennas.

5.2 Constrained Media

At some loss of flexibility because of the requirement to be attached to the physical media, guided or constraining media such as wires, cables, and optical fibers reduce or eliminate many kinds of channel distortion, attenuation, and interference.

5.2.1 Limitations on Constrained Media The communication of information in constrained media can be thwarted by four basic kinds of problems. First, the signals can become too weak to be useful—*attenuation.* The second kind is the corruption of the signal by noise, or interference; the third is *delay;* and the fourth is various kinds of *distortions,* including echos.

5.2.1.1 Attenuation. For wireless communications there are several ways in which signals can be attenuated. First, and most fundamental, is free-space loss that is an inverse-square law in distance and is the result of the geometric divergence of the signal from its source. This was discussed in Sec. 5.1.1. Also discussed there is attenuation due to absorption, principally by water vapor and oxygen. Finally, ducting and temperature inversions can cause attenuation where atmospheric variations divert the signal from the receiving antenna. In guided channels, attenuation is caused by absorption of the electromagnetic signals by the guiding media, such as metallic wires, cables, and/or optical fiber. The problem is not only the weakening of the signal but also the distortion caused by the variation of attenuation with frequency. Equalization techniques are often used to correct for this latter problem.

5.2.1.2 Noise. The two principal kinds of noise are *white* or *thermal noise* and *impulse noise*. The first is characterized by a power spectrum that is constant with respect to frequency at least over some band; the second, by random spikes of interference. The signal of interest can also be interfered with by other signals. *Cross talk* refers to the coupling of signals from other channels into the channel of interest. *Intermodulation* is interference resulting from the nonlinearity of frequency-division multiplexing giving rise to spurious frequencies. Finally, *echos* occur at impedance mismatches in channels. A common example occurs at the conversion of four-wire telephone transmission to two and conversely. Echos are particularly troublesome with satellite communication because of the long propagation delays. *Echo cancellers* and *suppressors* are devices designed to ameliorate this problem.

5.2.1.3 Delay. In a communication channel, signals are delayed, at a minimum, by the propagation time. In space or air, the signal propagates at very close to the speed of light, $c = 300\,000$ km/s. In optical fibers, the signal propagates at a speed determined by the index of refraction; the speed is c/ν, where ν is the index of refraction, which is about 1.47. For coaxial cable and wire pairs the situation is more complex. Especially for wire pairs, the speed of propagation varies strongly with frequency. This causes distortion as well as delay. Again, equalization techniques are used to combat the variability of delay with frequency.

5.2.1.4 Distortion. A common cause of signal distortion is the variation of features of signal transformation with frequency. For example, both propagation speed and attenuation vary with frequency, causing distortion. *Intersymbol interference* is the name given to the distortion causing the smearing of one pulse or other signal element into adjacent ones.

5.2.2 Twisted-Pair Cables

A *twisted-pair cable* consists of two insulated copper conductors twisted together. For multipair cable assemblies, the individual cable pairs are grouped in units or concentric layers to form the core of the cable, and adjacent pairs are twisted at different pitches to minimize interference between pairs.

The attenuation of twisted-pair cables depends on its series resistance, series inductance, and shunt capacitance. Other factors that influence the attenuation characteristics are the frequency-dependent skin effect and temperature change. To improve the frequency response for analog voice, loading coils (inductors) are usually inserted at 1.2-km intervals; however, these loading coils interfere with the use of twisted pair for digital communication. Typical attenuation values for a 0.4-mm (26-gauge) twisted pair is 8 dB/km at 10 kHz, 15 dB/km at 100 kHz, and 40 dB/km at 1000 kHz. Corresponding values for a 0.66-mm (22-gauge) twisted pair are 4 dB/km at 10 kHz, 6 dB/km at 100 kHz, and 20 dB/km at 1000 kHz.

Twisted pairs are the most common transmission medium linking individual telephones with a central office. Communication is analog with frequency-division multiplexing. In England, shielded twisted-pair cables are also used for cable TV distribution. Each pair carries a single TV channel, and channel assignment is demand based.

In the last 30 years, twisted-pair cables have also been used for digital transmission. In the United States, digital T-carrier systems operate over twisted-pair cables at rates up to 6.312 Mbps (T-2), with repeater distances of approximately 1.2 km. Because of higher loss and greater cross talk, the use of twisted-pair cables at transmission above 8 Mbps becomes undesirable, although twisted pair is used for short distances within buildings at up to 100 Mbps for local-area networks. Coaxial cables can be used for such applications, up to 500 Mbps. However, with the evolution of optical-fiber cables, new installation of twisted-pair or coaxial cable digital links is economically and operationally undesirable.

5.2.3 Coaxial Cable

A coaxial cable consists of an inner conductor surrounded by a concentric outer conductor. The two copper conductors are held in place and insulated by a dielectric material. A standard cable size for long-haul transmission has inner and outer conductor diameters of 2.6

and 9.5 mm, respectively, usually expressed as 2.6/9.5-mm cable. Other sizes commonly used are 1.2/4.4-mm and 0.7/2.9-mm cables.

The attenuation of a coaxial cable is proportional to its resistance. Alternating currents flow only in the outer layer of a conductor, with the thickness of the conducting layer being inversely proportional to the square root of frequency. This is known as the *skin effect*. As a consequence, the effective cross section of a coaxial cable decreases with frequency, and the attenuation correspondingly increases. One finds that the attenuation in dB/km of a coaxial cable is given by $\alpha = (A + Bf^{1/2} + Cf)$ dB/km, where A, B, and C are constants that depend on the cable geometry and f is the frequency in MHz. For a 2.6/9.5-mm cable, $A = 0.0150$, $B = 2.4235$, and $C = 0.0029$, giving 2.4 dB/km at 1 MHz and 19.0 dB/km at 60 MHz.

Prior to the evolution of optical-fiber technology, almost the entire long-haul telephone network in the United States was based on coaxial cables. The transmission mode was analog, with frequency-division multiplexing. Each voice channel was limited to 4.0 kHz bandwidth. Modulation was single sideband. The first long-haul L1 system was placed in service by AT&T in 1941. It used eight coaxial units per sheath, each carrying 720 voice channels, for a total capacity of 2160 full duplex channels. It was followed in 1953 by the L3 system with a capacity of 9300 voice channels. The most advanced system, the L5, was placed in operation in 1973. It uses 20 active coaxial units per sheath with two spares. Each cable has a capacity of 10 800 voice channels in one direction for a total capacity of 108 000 full duplex channels. AT&T's L multiplexing scheme uses frequency-division multiplexing in a hierarchal fashion to package the channels. A "group" of 12 message channels (voice or data) contains 12 inverted 4.0-kHz sidebands. Groups use 48 kHz of spectrum. A "supergroup" made up of five groups requires 240 kHz. A "mastergroup" of ten supergroups with guardbands is assigned 2.520 MHz. Finally, a "jumbogroup" of six mastergroups (and 36 000 voice channels) uses 16.894 MHz. Three multiplexed jumbogroups with adequate guardbands using the band from 3.124 to 60.556 MHz and additional single-frequency control signals form an L5 line.

Because of the strong frequency dependence of its attenuation, a coaxial cable has little bandwidth; however, its nominal bandwidth can be increased substantially by equalization techniques. For example, it is capable of carrying a multitude of frequency-division multiplexed signals since each is only 4.0 kHz in bandwidth. To ensure that all signals arrive at the receiving end with approximately equal power, equalizing amplifiers are used. To achieve toll-grade signal-to-noise quality, the L5 system requires equalization of 18 dB/km at the maximum frequency of 6.9 MHz. In addition, automatic adjustments in amplifier gain are needed to compensate for variations in cable attenuation with temperature. Even with those controls, there are still variations in attenuation and phase shift over the 4-kHz bandwidth of a single channel. As a consequence, dedicated conditioned lines must be used when amplitude-shift–keying or phase-shift–keying modems are used to transmit high-speed data over a voice channel. An alternative approach is to use hand-shake modems in which the modems negotiate at the initiation of a session equalization settings for the specific channel in use.

In view of the system complexity, large space requirements, high power consumption, limited capacity, and incompatibility with digital transmission, long-haul coaxial cable systems are being replaced worldwide by optical-fiber links. Cable television, which uses coaxial cable almost exclusively for its distribution system, is also switching over to optical fibers.

5.2.4 Optical-Fiber Communications

Light-wave communication over optical fibers is a major new technology that is having a profound impact on voice and video transmission, telephone systems, computer interconnections, instrumentation, data links, and telecommunication networks. The emergence of this technology was made possible by the dramatic progress achieved during the last 20 years in the development of low-loss and wide-bandwidth optical fibers, semiconductor laser diodes, and sensitive photodiode detectors.

An optical fiber is an all-dielectric waveguide that uses total internal reflection to confine the electromagnetic signal within its core (see FIBER OPTICS). This type of confinement at optical frequencies results in very low signal attenuation and extremely wide bandwidth. Moreover, since the wavelength of the propagating wave is of the order of 1 μm, the fiber cross-section dimensions are small, 125 μm in diameter. A schematic of an optical-fiber link is shown in Fig. 2. It consists of a laser transmitter, which converts the electronic signal into a corresponding optical signal that is coupled into the core of the fiber; a fiber link that guides the light wave to the receiving end; and an optical receiver, which converts the optical fluctuations back to an electronic signal. Thus, the communication, end to end, is electronic, but the link uses light waves for signal transmission. This results in a communication link that offers numerous advantages in comparison with other terrestrial or underwater transmission networks.

1. Optical transmission is immune to any ambient electrical noise, ringing, echoes, or electromagnetic interference and does not generate any of its own electrical noise. Moreover, fiber-optic communication does not present any problems of cross talk.
2. One fiber-optic filament, several mils in diameter, can replace a copper wire several millimeters in diameter. This savings in size and weight is especially important for underwater cables and in areas of overcrowded transmission wires such as in urban areas.
3. Optical cables are safe to use in explosive environments and eliminate the hazards of short circuits in metal wires and cables. Optical systems can be designed to have total electrical isolation. Thus, equipment used now for electronic cables that protects against grounding and voltage problems can be eliminated. Moreover, properly designed optical transmission lines and couplers are relatively immune to adverse temperature and moisture conditions.
4. Most importantly, optical fibers have very low attenuation and extremely wide bandwidth. It is this availability of wide bandwidths that made it possible to convert the common-carrier telephone system from the analog transmission mode to digital signaling and network integration, and, in addition, to increase the overall system capacity from 100 000 voice channels in the late 1960s to the multimillion-channel capacity of today. Also, low attenuation makes it possible to design repeaterless optical-fiber links up to 250 km in length.
5. The capacity of optical-fiber links, once installed, can be upgraded by increasing the bit rate of the transmitted signal (up to 10 Gbps with today's technology) and/or using wavelength division multiplexing; see Sec. 3.1.
6. The development of optical amplifiers made it possible to design "transparent

FIG. 2. Basic fiber-optic communication link. (Incoherent Optical Communication Link-Intensity Modulation)

pipe" undersea links of up to 6000 km in length. Such communication links do not use electronic regenerators and thus require no high-speed circuitry (except at the transmitting and receiving ends).

Optical fibers are cylindrical in shape. To confine the light wave, the dielectric inner core of the fiber is embedded within a dielectric material of a lower refractive index. The outside diameter of this cladding is standardized at 125 μm. When the refractive index of the core is uniform, the fiber is known as a *step-index fiber;* the fiber is *graded index* when the refractive index of the core region decreases continuously from its maximum value at the core axis.

The propagation characteristics of an optical signal guided by the fiber are determined by Maxwell's equations. When the core diameter is large, say 50 μm, a multitude of different field distributions, or modes, can propagate, and the fiber is "multimode."

To reproduce data accurately, light pulses must be kept separate and distinct with correct shape and spacing during transmission. In a multimode fiber the signal is spread among the many modes. Since each of the modes propagates with a slightly different speed, they will arrive at the receiving end at different times. This arrival-time variance results in a distorted signal and limits the frequency that can be transmitted. Since "modal dispersion," or pulse spreading, is linear with distance, the fiber is characterized by a length-bandwidth product, LB(3 dB), that is, by the product of its length L by the 3-dB bandwidth B(3 dB) of frequencies for which the transmitted signal power is greater than one-half of the signal power at low, near zero, frequencies. This results in a bandwidth that is inversely proportional to the fiber length. Multimode step-index fibers have a length-bandwidth product of only 10 MHz-km and are therefore of little use. However, multimode graded-index fibers have a length-bandwidth product of 200–1000 MHz-km and are at the present used extensively in the United States for local-area networks and other short-haul links.

When the core diameter of the fiber is reduced to approximately 8 μm, only a single electromagnetic-field distribution or mode can propagate. The fiber is then *single mode* and has, theoretically, at least, infinite bandwidth. All long-haul communication links use single-mode fibers.

Semiconductor lasers are used to convert the electrical signal into an optical signal carried by the fiber. Such sources are not single frequency but have a broad spectrum. For example, a typical laser diode operating at a wavelength of 1300 nm (corresponding to a frequency of 230 TH) has a spectral width of 3 nm, or 530 GHz. Even an expensive distributed-feedback laser diode used for bit rates above 1 Gbps and for cable television links has a spectral width of 0.1 nm, or 20 GHz. Moreover, the spectral components emitted by the source are not correlated in phase. Accordingly, optical communication is different from conventional terrestrial or wireless communication; it is incoherent. That is, what is being modulated by the signal is not the electric field or the magnetic field, but the optical power of the source. Correspondingly, direct detection is used to recover the signal at the receiving end. There is no local oscillator, and there is no mixing. The broad spectral width of the source leads to other consequences as well.

The speed of an electromagnetic signal within a dielectric medium depends on its refractive index, which is wavelength dependent. In addition, when a signal is guided, its velocity also depends on the physical dimensions of the waveguide relative to the wavelength. Accordingly, the different spectral components of the source propagate with slightly different speeds, and the signal will disperse. This is known as chromatic dispersion and limits the fiber bandwidth. The resulting length-bandwidth product of the fiber link depends on two factors: the properties of the fiber and the spectral width of the source. The narrower the source, the greater is the length-bandwidth product of the link.

Figure 3 shows the attenuation and dispersion of silica-based optical fibers including the newer dispersion shifted fibers (DSFs). For single-mode fibers there are two favorable transmission regions within the optical spectrum. The first, the (1300 ± 50)-nm window, is 18 000 GHz wide. Here, the fiber attenuation is 0.4 dB/km, and the chromatic dispersion is nearly zero for conventional step-index single-mode fibers labeled SSMF. Thus, the length-bandwidth product of a fiber link operating in the 1300-nm region is

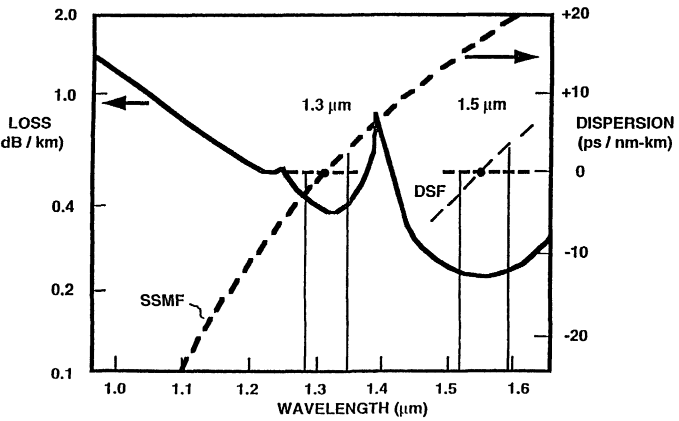

FIG. 3. Single-mode fiber attenuation and dispersion.

very high, regardless of the spectral width of the source. Initially, all fiber links operated in this window. However, lowest fiber attenuation occurs in the (1550 ± 50)-nm window, 12 500 GHz wide. Here, the chromatic dispersion is finite, but the attenuation is only 0.18 dB/km, allowing for an increase in the repeaterless link length to almost 250 km. Sources of very narrow spectral width are needed to operate at gigabit-per-second rates.

There has been extensive research to develop polarization-independent optical amplifiers for the 1300- and 1550-nm spectral regions. The effort became successful with the evolution of reliable erbium-doped optical-fiber amplifiers for the 1550-nm region. In contrast to electronic amplifiers, optical amplifiers raise insignificantly the noise level of the signal. This made it possible to implement passive fiber links up to 250 km in length and to design amplifier-based links thousands of kilometers in length. Such links provide a "transparent pipe" communication link and, with the exception of the transmitting and receiving ends, require no high-speed circuitry. In addition, erbium-doped amplifiers have a broad gain spectrum so that a single amplifier can be used to amplify a multiple-channel wavelength-division multiplexed (WDM) signal and eliminate the need for multiple wavelength-division splitters and combiners at each amplifier site.

It was pointed out earlier that the length-bandwidth product of optical fibers is inversely proportional to the product of the spectral width of the source and the chromatic dispersion constant of the fiber at the particular wavelength of operation. This seems to indicate that the fiber bandwidth becomes infinitely large when the spectral width of the source is reduced to zero. However, even a monochromatic source when modulated at, say, a 1-Gbps rate will result in a signal with a spectral width of 2 GHz. Accordingly, the length-bandwidth product with chromatic dispersion depends not only on the spectral width of the source but also on the information bandwidth. High-speed long-haul links must therefore use fibers that are nearly dispersion free at 1550 nm. All newly installed long-haul routes use such "dispersion shifted" or DSF single-mode fibers. In 1996, AT&T installed two transatlantic fiber cables, each 6000 km in length, and two transpacific cables, each 12 000 km in length. In addition, to complete the loop, a submarine cable was installed between England and Japan. Each of the five cables uses six dispersion-shifted fibers and in-line erbium-doped optical amplifiers (without regenerators), and is designed to operate at an initial rate of 5.0 Gbps to carry 64 512 duplex voice channels per fiber pair. Additional submarine cables to be installed in 1998 will use six WDM fibers at 5.0 Gbps each to carry 518 096 voice channels per fiber pair. It is of interest to note that for proper operation, the transpacific link requires a length-bandwidth product that is in excess of 30×10^{12} Hz-km. This is six orders of magnitude higher than the bandwidth that can be achieved with high-grade coaxial cables.

To facilitate global communications and to establish a flexible architecture capable of accommodating applications with a variety of transmission rates, an international Synchronous Optical Network (SONET) fiber transport standard was introduced by Bellcore in 1985. It establishes a standard multiplexing format using any number of 51.84-Mbps signals as building blocks. The lowest level is OC-1 with a data rate of 51.84 Mbps; OC-48 has a data rate of 48 × 51.84 Mbps = 2488.32 Mbps. SONET also defines a synchronous multiplexing format for carrying lower-level digital signals. The synchronous structure allows one-step bit-interleaved multiplexing and demultiplexing, and greatly simplifies the interface-to-digital switches and add-drop multiplexers.

6. THE TELECOMMUNICATIONS INDUSTRY AND ITS FUTURE

The two most important trends in modern telecommunications technology are toward the supporting of multiple services on broadband facilities and the use of wireless communication to untether the user from being wired to the network. Local-area networks have proliferated. Because they operate at rather high data rates, 3–100 Mbps, they are difficult to interconnect over long distances. Moreover, enhanced services beyond voice and data, such as image and video communication, have increased the demands. Too, the increasing use of the client–server approach to computing makes rapid communication essential. Fortunately, the increasing prevalence and high performance of fiber-optic transmission (up to 3 Gbps) make it plausible to support the required transmission. Switching is another matter. For most purposes that involve the processing of information on fiber links, the signal has to be converted from light to electronic forms for processing. This coupled with the high rates at which fibers operate make switching the bottleneck. Ultimately, the solution will be the development of optical processing so that the information can be processed in its form as light without conversion to electronic form. The erbium optical amplifiers discussed earlier are the first such devices. However, a full complement of optical processing devices is some time off. Developing such devices may require new, fundamental physical insights. In the near term, new protocols and standards are being developed to reduce the load on the switches. Not only is modern fiber-optic communications carried out at very high rates, but the channels are comparatively error free. This makes it possible to perform less error checking. The X.25-type packet switching of the 1970s and early 1980s usually involved error checking across each link of a network as well as end to end. The communication methods developed to meet the challenges of high-speed optical channels carrying integrated services do much less error control—detection and correction. The asynchronous transfer mode (ATM) protocol has been developed to reduce the load on the communication switches and to support real-time broadband services such as video conferencing. The primary data unit for this protocol is a 53-byte cell, 48 bytes of information and 5 bytes of overhead. Every cell is exactly the same length and format. This makes it possible to accomplish most of the switching functions in hardware. The small size reduces the switching latency so that high–data-rate real-time traffic can be supported. Much of the flow control and error control of the previous generation (X.25) of packet switching is missing in ATM because the relatively error-free performance of fiber-optic channels does not require it. It is believed that ATM will be able to support all services at very high-speed, broadband data rates.

The immense popularity of the Internet and its exponential growth—the number of computers (hosts) on the Internet has doubled annually for the last 15 years—will provide the demand for the high-performance and broadband networks made possible by fiber optics. In addition, users will demand the flexibility of wireless terminals, and so the technologies discussed here are not merely driven by what is technically possible but they will find a market as well.

GLOSSARY OF ACRONYMS AND TECHNICAL TERMS

Amplitude Modulation (AM): A method of superimposing a signal on a carrier wave by varying (modulating) the amplitude of the carrier wave.

AMPS: Advanced mobile phone system.

Analog Data: Data represented by a continuously variable physical quantity that is directly related to the data.

Asynchronous Transfer Mode (ATM): A special form of packet switching designed for high-speed networks. Transmission is based on small, fixed-size (53 octet) packets called cells. This reduces latency in switches so that multiple modes of information can be transmitted, including real-time video.

Attenuation: A decrease in the amplitude of a signal in transmission from one point to another.

Baseband Transmission: A method of using a transmission facility where the information is applied directly to the facility without the use of a carrier.

Carrier: A single frequency that is impressed with a second information-bearing signal by perturbing the characteristics of the carrier such as its frequency, amplitude, and/or phase.

CDM: Code-division multiplexing.

CDMA: Code-division multiple access.

Circuit Switching: A method of routing traffic through a communication network where a dedicated path is reserved from source to destination and bandwidth is guaranteed for the duration of the information transfer.

CT-2: Second-generation cordless telephone.

Cyclic Redundancy Checksum (CRC): A method for detecting errors in transmitted data. Additional redundant information in the form of the remainder of a modulo-two division is added to the information being transmitted to allow the detection of errors in transmission by the receiver performing a consistency computation.

DAMA: Demand assignment, multiple access.

Digital Data: Data consisting of a sequence of elements chosen from a discrete set of values.

Dispersion-Shifted Fiber (DSF): Optical fiber designed to make the region of minimum dispersion coincide with the region of minimum attenuation at 1550 nm.

Echo Canceler: A device to identify and filter out echoes.

Echo Suppressor: A device that turns off reverse transmission in a channel to eliminate echoes.

Equalization: Techniques to compensate for distortion due to frequency dependence of attenuation and/or delay.

FAMA: Fixed assignment, multiple access.

FCC: Federal Communications Commission (U.S.).

Free-Space Path Loss: The loss in signal strength in wireless communication resulting solely from the geometric divergence of the radiation as a function of distance.

Frequency Diversity: A feature of wireless systems where the received signal is selected from or derived from several signals that are transmitted on different carriers to provide more robust communication.

Frequency-Division Multiple Access (FDMA): The sharing of a transmission facility by dynamically allocating channels derived by frequency-division multiplexing to users.

Frequency-Division Multiplexing (FDM): The sharing of a transmission facility by dividing its bandwidth into narrower bands, each of which is used to carry a subchannel.

Frequency Modulation (FM): A method of superimposing a signal on a carrier wave by varying (modulating) the frequency of the carrier wave.

Frequency-Shift Keying (FSK): A method of superimposing a digital signal on a carrier wave by varying (modulating) the frequency of the carrier wave.

GSM: Global System for Mobile or Général Speciale Mobile.

Impulse Noise: Random noise characterized by high amplitude and short duration, often due to vehicle ignitions, lightning, and various other kinds of sparking phenomena.

Intersymbol Interference: The impairment in the transmission of digital information resulting from the overlap due to distortion of adjacent digital symbol representations.

LEO: Low Earth orbit for satellites.

Modem (Modulator/Demodulator): A device for converting a digital signal into analog form (modulation) for transmission and converting the analog form back to digital (demodulation) upon reception.

Modulation: The process, or its result, of perturbing characteristics such as amplitude, frequency, or phase of a carrier to transmit a message signal.

Multipath: In wireless transmission, the superposition of direct and reflected signals with varying delays.

Packet Switching: Routing of data in networks in blocks of data called packets that have a fixed upper bound in size. Each packet has its own address to specify its destination. Channels may be used by packets of different communications in an interleaved fashion. Packets are successively read into the memory of switches and then retransmitted to the next switch on the path from source to destination.

PCS: Personal communications services.

Phase-Shift Keying (PSK): A method of superimposing a digital signal on a carrier wave by varying the phase of a carrier wave among a finite set of phases.

Pixel (Picture Element): A bit-mapped image is represented by a rectangular grid of points. Associated with each point is a color value, black/white, gray-scale value, or color, depending on the type of image. Each of these points with the associated color value is a pixel.

Pulse Code Modulation (PCM): A two-step method for representing analog information digitally. In the first step, the analog information is sampled at a rate higher than twice the bandwidth of the information. Next, the samples are discretized into a representation by a fixed number of bits.

Quadrature Amplitude Modulation (QAM): A modulation scheme for sending binary information on an analog channel using a combination of phase-shift and amplitude-shift keying.

Single-Sideband Transmission: Transmission where one of the two sidebands of a carrier signal is suppressed.

SONET: Synchronous optical network.

Space Diversity: A feature of wireless systems where the received signal is selected from or derived from several signals that are physically separated in order to provide more robust communication.

Space-Division Multiplexing: A method for sharing communication resources where signals are separated by physical separation.

Statistical Multiplexing: A transmission facility shared by allocating time slots to channels upon demand using time division. The sum of the peak rates of the channels may be larger than the rate of the shared facility, but not the sum of the average information rates.

Thermal Noise: Ubiquitous noise resulting from the thermal movement within matter.

Time-Division Multiple Access (TDMA): The sharing of a transmission facility by dynamically allocating channels derived by time-division multiplexing to users (usually in wireless communication).

Time-Division Multiplexing (TDM): The sharing of a transmission facility by allocating it sequentially and in rotation among the users.

Wavelength-Division Multiplexing (WDM): A name for frequency-division multiplexing in the optical region of the spectrum.

INTRODUCTION

The Concept of Temperature

One of the most frequently asked questions in sci.physics, the physics user interest group on the Internet, is "What is temperature?" Fortunately, as the author responsible for sci.physics explains, we have a good intuitive concept of temperature: "Our intuitive notion is that two systems in thermal contact should exchange no heat, on average, if and only if they are at the same temperature." The author then describes the total energy of the system, the many possible internal states of a thermodynamic system, and division of energy in the two states that are in thermal contact.

This concept is a useful one, because it defines temperature by examining not one, but two systems in thermal contact. For temperature measurement and control, this is useful to bear in mind, because there are always at least two systems in thermal contact any time one wishes to measure and/or control temperature. Examples: a mercury thermometer (system 1) is used to determine the extent of a person's fever (system 2); thermocouples use the contact between the junction (system 1) and the object (system 2) to measure an object's temperature accurately; a water jacket (system 1) is used to cool controllably a hot reactor (system 2).

Motivations: Why Good Temperature Measurement and Control Is Needed

In many areas of science and industry, temperature measurement and control is crucial. Our bodies are a good example. Think of how poorly human beings would function if their body temperatures increased (or decreased) a few degrees away from the 37 °C set point. Weather conditions, which,

digital Encyclopedia of Applied Physics

of course, are virtually impossible to control but very extensively measured, determine everything from how we dress to leave for the day to who might win an important political election.

Not only is temperature measurement and control important for its own sake; it is also important for what it can tell us about physics, chemistry, biology, or engineering. Calorimetric measurements, measures of heat and/or heat flux, are usually made by comparing two or more temperature measurements, often closely spaced in terms of time or physical location. Therefore, since the basic calorimetric measurement is a temperature difference, high accuracy and precision are required. Recently, calorimetric measurements have become very sophisticated (Mettler, 1991; Basalik, 1993), allowing scientists and engineers to determine accurately, for very complex processes, reaction-kinetic parameters (Moritz, 1988; Schmidt and Reichert, 1988), heat-transfer coefficients (Machado, 1994; Kumpinsky, 1992), mixing efficiency (Fasano *et al.*, 1991), and engineering scale-up parameters (Choudhury and Utiger, 1992).

The above examples are enough to illustrate the point of why good temperature measurement and control can be important. In what follows, a single specific scientific problem is examined in detail, to trace exactly why and how critical these measures and control approaches can be.

Example of the Importance of Temperature: Molecular-Weight Control in Polymers

Temperature is almost always a critical variable in controlling the molecular-weight distribution for polymers. Generally, the goal of a polymer scientist is to produce polymers with well-characterized (and usually high and narrow) molecular-weight distributions. This leads to well-characterized, well-defined polymer materials, with the required strength and resilience to meet applications needs. Sometimes, however, the properties required suggest that it is best to make a polymer consisting of a mix of different molecular-weight distributions; for example, narrow, short-chain polymers mixed with a second polymer exhibiting a much higher and broader molecular-weight distribution are usually good adhesives.

To get a low molecular-weight distribution, free-radical polymerizations are carried out at high temperatures, where many radicals produce many short chains. Conversely, to get high molecular-weight polymers, the same sort of polymerizations can be run, but at temperatures just low enough to produce a few free radicals, which in turn produce a few long chains of polymer. This is usually more difficult, because few radicals can also mean slow, sluggish kinetics.

Industrial processes involve many variables, many products, and many requirements, such as requiring rapid, safe, stable production of high molecular-weight polymers at very high yields. Such requirements make the task of producing a high molecular-weight polymer an even more daunting task, with many subtleties involved. Temperature measurement and control becomes even more crucial.

The article by Sack *et al.* (1973) describes some of these subtleties and provides reasons for why temperature control is so crucial. Their analysis of key experiments concludes, for instance, that those temperature variations that maximize the breadth of molecular-weight distribution are step changes between the minimum and maximum allowable temperatures in a system in order to achieve a bimodal distribution of sizes (Sack *et al.*, 1973). Moreover, these authors conclude that, on average, temperature variations have a much greater effect on breadth of molecular-weight distributions for chain-addition polymerizations than either the residence-time distributions or micromixing. Finally, they discuss different types of polymerizations and how temperature for these different types of processes should be tuned or manipulated in time so as to achieve just the right distribution of molecular weights.

Besides polymerization processes, there are many other areas where temperature control is even more critical: other reaction engineering disciplines, biotechnology, nuclear engineering, aerospace, materials processing, separation technologies, fermentation processes, and agriculture. The reference book *Temperature Control Principles for Process Engineers* (Dougherty, 1993) contains many such examples. Space constraints prohibit providing detailed examples from each of these areas of technology; but whenever possible, specific examples from these and other areas will be integrated into the following sections on measurements and control. In discussing applications, commercial products are occasionally mentioned, but this article by no means wishes to recommend one product over another. The point of the applications is to stress the main reasons to do good temperature measurement and control: to do or make something of value better, cheaper, and/or faster, or to do the kind of research that will allow others to improve how things are made or done at some time in the future.

1. MEASUREMENT TECHNIQUES

For the reasons outlined above, it is not surprising that temperature was one of the first variables ever to be measured in the process field. Over the years, it has been sensed in just about every way imaginable. Virtually any physical property that changes with temperature has, at one time or another, been used as a basis for this measurement (Smith, 1995). Many basic phenomena form the basis for most temperature measuring instruments. These include

1. the thermoelectric effect;
2. changes in electrical resistance;
3. radiant energy; and
4. changes in physical dimension or characteristics of liquids, metals, and gases.

Among the many methods still used in industry today are thermocouples (T/Cs), resistance temperature detectors (RTDs), thermistors, electronic temperature sensors, bimetallic devices, filled devices, infrared (IR) devices, and acoustic pyrometry (Smith, 1995). This article examines many of these methods in detail to explain how they work and to provide ideas on how and under what conditions each can be applied. In addition, examples of their use and applications to solve important problems are also provided.

1.1 Thermocouples

An electric current flows in a closed circuit consisting of two dissimilar conductors joined at both ends if the two junctions are at different temperatures (Anon., 1989a). Thomas Seebeck made this discovery in 1821 (Katz, 1993). If the circuit is broken, the net open-circuit voltage (the Seebeck voltage) is a function of the junction temperature and the composition of the two metals. That is, the magnitude of the voltage that causes current flow is a characteristic of the two metals and a function of the temperature difference, $T - T_R$. If T_R is known, the temperature T is determined for a given pair of metals by measuring the voltage developed (see Fig. 1). The voltage output is of the order of millivolts. A millivoltmeter, actuated by the current in a circuit of known resistance R, measures the voltage, which is related to the current I and resistance R by Ohm's law: $V = IR$. Manufacturers calibrate for a certain thermocouple resistance. They strive for the highest internal resistance consistent with the ruggedness required for measurements under all sorts of environments (Anon., 1992).

Output of a T/C is a function of the temperature difference, $T - T_R$. If the temperature is to be known accurately, the reference temperature must be known or its effect compensated for. Compensation shifts the

zero of the instrument such that it reads T_R whenever there is no input to the instrument.

Thermocouples are flexible; they are used to make sensors of special, often unusual shapes. They are generally recommended for use at very high temperatures or where temperature must be measured over very wide spans. When installing T/Cs, attention must be paid to the type of wire connecting the probe to the instrument. Special extension wire is used to ensure high measurement accuracy. Best accuracy is achieved when the measuring target is close to the junction point.

Thermocouples are characterized by the different types of materials used as the two dissimilar conductors. Listed in Table 1 are many of the most common types, together with the range of temperatures over which they are applicable for measurement (Hall, 1990; ASTM, 1987).

Thermocouple wire is usually color-coded in a standard way for the different thermocouple types; for example, type J thermocouple wire is usually red (positive) and white (negative). The different materials may be chosen because of environmental or corrosion considerations; for example, K- and E-type thermocouples are not recommended for sulfurous, reducing, or strongly oxidative environments (Wang, 1991).

Tables exist to show the variation of voltage with temperature for these and other different types of thermocouples. Generally, the voltage difference for a 1 °C temperature change is in the range of microvolts; this tiny voltage difference means that high accuracy is not easy to attain with T/Cs. Accuracy is typically only about ±2 °C, although this can be improved by using special high-accuracy probes and careful compensation. Some typical calibration tolerances are listed in Table 2 for selected thermocouple types (ASTM, 1987). At subzero temperatures, these tolerances will be slightly worse.

Table 1. Basic thermocouple types, materials of construction, and temperature ranges of applicability.

Type	Materials	Temperature range
B	Pt-30% Rh vs. Pt-6% Rh	0 to 1820 °C
E	Ni-10% Cr vs. Constantan	−270 to 1000 °C
J	Iron vs. Constantan	−210 to 1200 °C
K	Ni-10% Cr vs. Ni-5% Al, Si	−270 to 1372 °C
R	Pt-13% Rh vs. Pt	−50 to 1768 °C
S	Pt-10% Rh vs. Pt	−50 to 1768 °C
T	Cu vs. Constantan	−270 to 400 °C
N	Ni-14% Cr-1.5% Si vs. Ni-4.5% Si-0.1% Mg	−270 to 1300 °C
WRe	W-5% Rh vs. W	−270 to 2316 °C

Table 2. Specifications for tolerances for various types of thermocouples.

Type	Standard tolerance (°C or %)	Special tolerance (°C or %)
J	±2.2 or 0.75	±1.1 or 0.4
T	±1 or 0.75	±0.5 or 0.4
E	±1.7 or 0.5	±1 or 0.4
K	±2.2 or 2	±1 or 1.0

The average wire diameter is dictated by the thermocouple and the required measurement response time. Some suggested upper limits for the average wire sizes for various protected thermocouples are listed in Table 3 (Anon., 1989a).

T/C construction varies and is dependent on the required application. Figure 2 shows the wide variety of shapes and sheaths for various applications. The flexibility of thermocouples allows designers to fabricate them to make measurements at very high- or very low-temperature regimes, at the surface of a material, in highly corrosive environments, around corners, or at very special locations. There are ceramic-beaded, insulated, and metal-sheathed, mineral-insulated T/Cs. Ceramics allow use at very high temperatures but lack some flexibility because of reduced mechanical strength and slow response times. To protect thermocouples from highly hazardous or corrosive environments—say, those encountered in certain chemical

FIG. 2. Thermocouples come in a wide variety of shapes and sizes to meet the required application needs (from Wahl, 1995).

applications—thermowells, which are simple, closed-end tubes, are used to encase the thermocouples.

Figure 2 shows some special-purpose thermocouples known as surface T/Cs. Some surface T/Cs use a special thermally conductive adhesive that allows them to be strapped onto pipes in order to infer temperatures inside those pipes very accurately (Anon., 1995). Alternatively, by using thermowells to sheath the thermocouples having the same thermal properties as the surface wall, surface T/Cs can be very useful for making accurate heat transfer or calorimetric measurements (Fasano *et al.*, 1991).

Because accuracy and precision are key issues with T/Cs, the very low electrical signals involved require the use of some special techniques. One article (Hashemian and Peterson, 1993) describes how to carry out cross-calibration of thermocouples, account for moisture and inhomogeneities in circuits, use redundant measurements effectively, provide noise analysis, and use empirical correlations—all steps to improve thermocouple accuracy.

To improve thermocouple accuracy and precision, a reference thermocouple should be provided at an appropriate, known temperature to compare measurements with. Originally, the "reference" was provided using an ice-water bath maintained at 0 °C; so the practice became known as "cold"-junction compensation (Liptak, 1993; Samuels, 1995). Nowadays temperature compensation is done electronically, using appropriate software. In Sec. 2.6, compensation and other temperature-signal conditioning approaches will be treated in greater detail.

Some very special thermocouples can be used for high-temperature applications, such as measuring temperature in incinerators, ovens, and furnaces. Special-purpose T/Cs, however, may lack the signal-conditioning devices needed for compensation, linearization, or calibration.

1.2 Resistance Temperature Detectors

Industrial resistance temperature detectors (RTDs) are generally constructed of platinum, nickel, or copper. The basis for measurement is knowledge of how the resistance of these materials changes with temperature; an accurate resistance measurement yields an accurate temperature (see Fig. 3). Calibration is done directly in terms of temperature. The range of temperature measured depends on the type of construction, the type of insulation used for the sensor, and only secondarily on the type of metal used. The manner of winding the wire to avoid the effect of mechanical strains is also important in determining the range of temperature measurement (Anon., 1992).

Despite its high cost, platinum is the most popular material for RTDs; its resistance change with temperature is 0.0390% per °C. Less expensive RTDs can be constructed from Balco (an iron–nickel alloy), nickel, and copper. However, nickel has stability problems, and both Balco and nickel have problems with reproducibility. The problem with a typical copper RTD is that it takes up a lot of space (Clayton, 1993).

Resistance thermometers are inherently accurate; repeatability can be as good as ±0.02 °C; accuracy, better than 0.05 °C. The ability of these thermometers to measure temperature accurately over very narrow temperature spans, say, less than 0.5 °C, is their greatest attraction for critical process control applications. Four-wire measurements can be especially accurate and precise (Lewis, 1995). One instrument company claims to be able to calibrate RTDs to an accuracy of ±0.001 °C (Labs, 1989).

Most circuits (Lewis, 1995) used with resistance thermometer bulbs are similar to the classical Wheatstone bridge circuit (see Fig. 4). Two slidewires driven in tandem are used. Slidewire No. 1 maintains the arm of the bridge containing resistor C at a value equal to the bulb resistance. Compensation of the connecting wire is theoretically perfect. Perfection is limited by the accuracy of matching the resistance for lead wire L_2 with that at L_3. The battery voltage does not affect calibration but does affect sensitivity. Instead of batteries, nowadays solid-state devices, together with ordinary power supplies, are used to minimize failures and maintenance (Anon., 1992). Finally, four-wire RTDs, which use a current source and an additional lead wire, provide more accurate temperature measurements because they reduce the (nonlinear) effects of lead-wire length and resistance on voltage (Anon., 1989a).

An RTD is usually constructed as a fixed length of fine resistance wire wound on a glass or ceramic mandrel. However, recently, thin-film (and even thick-film) platinum RTDs are challenging the wire-wound types in certain applications. Wire-wound types, the most accurate types, are common in military/aerospace, food, beverage, chemical,

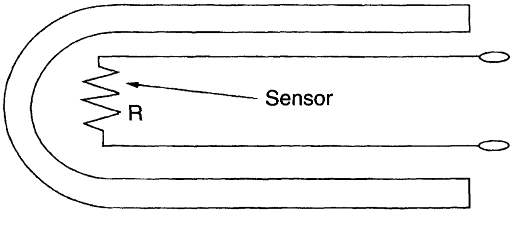

FIG. 3. Schematic of a resistance thermometer (courtesy of Katz, 1993).

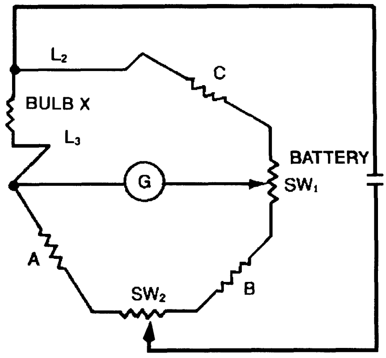

FIG. 4. A Wheatstone bridge used as a typical resistance bridge circuit for an RTD. The symbols L_i denote the three lead wires used; Sw_j denotes the two slidewires used to match the resistances (see text). G denotes a meter for measuring the voltage.

Table 4. Advantages of thermocouples and RTDs.

RTD advantages	T/C advantages
High accuracy; greatest over wide span	Modest accuracy
Relatively narrow spans (5 °C can be measured)	Very wide range (0–1000 °C)
Reproducibility unaffected by temperature change	Rugged
Short-term reproducibility better than T/Cs	Remote and versatile mounting
Compensation not necessary	Moderately stable
Handle suppressed ranges	Moderate cost
Relatively small sizes	Small sizes available also

Table 5. Disadvantages of thermocouples and RTDs.

RTD disadvantages	T/C disadvantages
More expensive	Low output signal
Limited above 1500 °F	Calibration changed by contamination
Less rugged	Electrical interference can be a problem
Self-heating can be problem	Calibration nonlinear over normal spans
Vibration can affect wire-wound types, whereas thin-film types are expensive	Higher installation costs (due to the need for special extension wires)

utility, plastic, and rubber applications. On the other hand, RTDs are not commonly used in metal processing, glass ceramics, or petrochemical applications. The reason: upper temperature limits of RTDs (about 850 °C) (Anon., 1989a) are well below the everyday working temperatures in these industries (Clayton, 1993).

Wire-wound RTD response times are fast (1–4 s), but the fastest thermocouples can respond much more rapidly. Still, with platinum (Pt) sensors and new, technologically advanced thin-film technology, it is now possible to create sensors that withstand 5 N of force and get Pt 100-Ω film elements down to $1.5 \times 5.0\ \text{mm}^2$. Response times can be as low as 0.07 s in water, or 5 s in air moving at a velocity of 1 m/s.

Ease of use is one factor that has led to RTDs growing in popularity relative to T/Cs. RTD signal levels are ten times higher than T/C levels (250 μV vs. 25 μV), so that they are less susceptible to noise. RTDs require neither compensation nor special lead wires. While T/Cs are generally priced lower, the extra accuracy afforded by RTDs can make costs nearly comparable in some applications.

On the other hand, making RTDs with stability, ruggedness, and accuracy is a complex process. One must take into account thermal expansion characteristics, material compatibility, heat transfer, ability to seal properly to prevent moisture penetration, and purity (it is especially important for platinum to be pure).

For temperature measurements in extremely cold environments (30–300 K), germanium resistance thermometers (GRTs), carbon-glass thermometers, platinum RTDs, and rhodium–iron resistance thermometers can all be used effectively. Germanium and carbon-glass sensors are nonmetallic RTDs. Below 30 K, special germanium-type sensors, while very expensive, can exhibit reproducibilities on the order of ±0.001 K (Labs, 1989).

Since RTDs and T/Cs are both popular means of measuring temperature, Tables 4 and 5 compare the advantages and disadvantages of RTDs and T/Cs (Kane, 1990). Table 6, a summary of typical RTD and T/C specifications, compares and contrasts these two popular methods of temperature measurement (Anon., 1992).

1.3 Thermistors

While most industrial resistance thermometers are RTDs, thermistors are resistance temperature sensors in which the resistance *decreases* with temperature, instead of

Table 6. A Summary of key thermocouple and RTD specifications.

Characteristic	RTD	T/C
Stability	0.005–0.05 °C	0.5–5 °C
Drift	Less than 0.1% in 5 years	0.5 °C/year
Range	−200–900 °C	−150–1100 °C
Sensitivity	0.2–20 Ω/°C	10–100 μV/°C
Output	1–6 V	0–60 mV
Power (100-Ω load)	0.04 W	2×10^{-7} W

increasing as most metals do. Additionally, the resistance change with temperature in thermistors can be enormous. When a device is required to have extreme sensitivity to changes in temperature, thermistors are to be recommended (Stockdale, 1992; Anon., 1992).

Thermistors are very sensitive probes that actually have not been very widely applied industrially. The best operating characteristics are for temperatures below 100 °C. Because they are so "sensitive" (negative temperature coefficient thermistors change as much as 4% per °C), they are often thought of as inaccurate, unstable devices. Yet, when used in a leg of an accurate Wheatstone bridge circuit, their sensitivity can be used to advantage to measure, precisely and accurately, very small temperature differences, mainly over narrow temperature spans (Trietley, 1989).

1.4 Filled Thermal Systems

Filled thermal systems can provide effective, efficient, and economical temperature measurement and control, provided such basic principles of selection, design, and installation are followed (Anon., 1992). Simple, inexpensive mercury thermometers can be both very accurate and very precise. Of course, response times can be very slow.

A filled-system thermometer makes use of the principle that most liquids and gases expand or try to expand as their temperature increases. A liquid or gas of known characteristics is totally enclosed, and the amount of expansion in the case of liquids or the pressure change resulting from the attempt to expand are measured. This gives a reading directly related to the temperature of the liquid or gas.

A bulb is exposed to the temperature being measured. It is connected by capillary tubing to a long, coiled, filled tube, known as a bourdon tube. Various types of materials are used as fill materials, depending on the application, but mercury, of course, is very commonly used.

A filled thermal application requires adherence to the following guidelines:

1. The right bulb sensing element for the temperature range to be measured must be selected.
2. The appropriate bulb shape and type must be chosen to allow proper installation, bulb immersion, and bulb protection; the smaller the temperature span, the larger the required bulb.
3. The bulb should be located in the right spot, i.e., exactly where the temperature is to be measured.
4. The bulb must be immersed completely in the medium of interest.
5. The bulb must be placed such that the medium surrounding the bulb and the material in the bulb (usually mercury) reach thermal equilibrium as quickly as possible.
6. The bulb should be protected from physical disturbance, damage, or sources of corrosion.

1.5 Bimetallic Thermometers

Bimetallic thermometers are also a useful, simple, and popular means to measure temperature accurately. Generally, bimetallic thermometers consist of a metal stem, which contains the bimetal sensing element wound up into a helical coil and located near the end of the stem. The metal stem is physically connected to a dial to provide an analog indicator of the temperature. The metal contacting the object or fluid whose temperature is to be measured is usually stainless steel and/or some other corrosion-resistant material. Accuracy is typically about ±1–2% of the scale reading of the dial. Typical bimetallic temperature ranges are −20–200 °C. Response times are reasonable: 40 s is typical. Some typical applications include boilers, cabinets, tanks, drums, piping, air conditioning units, refrigerators, and so on (Reotemp, 1987; Anon., 1989a). Bimetallic thermometers have limitations because they do not easily hook up to electronic computers and control systems and are somewhat limited in range and response times. Still, they represent a very accurate, low-cost, general-purpose sensor appropriate in a variety of different temperature measurement and control applications.

1.6 Infrared Temperature Sensors

Infrared thermometers, also called infrared pyrometers, measure the temperature of an object without touching it. This is useful when the object to be measured is in motion or too far away, too delicate, or too hot to touch. Radiation thermometry is often used in applications where contact thermometers fail. The major challenge is to minimize or compensate for such signal effects as target or background emittance, intervening flames, dust, and so on.

Radiation pyrometers make use of the fact that radiant energy is constantly being emitted by all materials (Love, 1993). The emitted radiation varies in a known way with temperature. Tables and graphs exist that show the shape of the radiated spectrum vs. temperature and wavelength. The peak power density moves to shorter wavelengths as temperature increases (see Fig. 5).

In practice, the energy from a hot object is collected by a lens and focused on a thermopile. This energy is a function of the absolute temperature of the hot object and its characteristic emissivity. Output of these devices is usually a voltage that varies with temperature raised to the fourth or fifth power.

Mathematically, the amount of this radiated power is determined by the following equation:

$$W = E\sigma T^4, \tag{1}$$

where W = spectral radiant exitance (radiation) (units of watts per square centimeter), E = emissivity, σ = Stefan–Boltzmann constant (5.67×10^{-12} W/cm^2), and T = temperature (K).

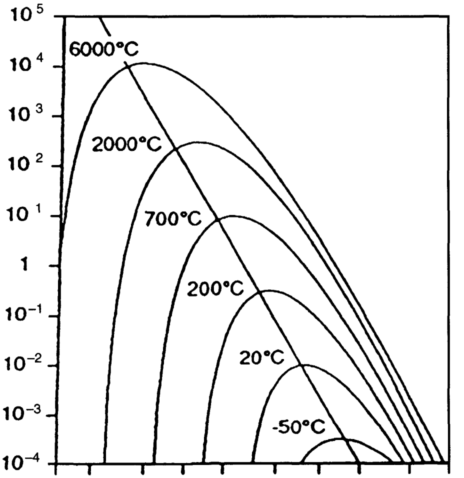

FIG. 5. Radiation power density decreases as a function of wavelength. Here maximum power densities for selected temperatures are shown.

Some appreciation should be gained for the dependence of radiation power on temperature. For example, a blackbody (emissivity of 100%) at 30 °C would have a radiation density of 5.4 mW/cm^2. That same blackbody at a temperature of 150 °C would have a radiation density of 139.2 mW/cm^2 (Walcutt, 1994).

Critical to the accuracy of an IR thermometer is the emissivity of the surface being measured. Emissivity is the measure of how effectively a surface radiates relative to an ideal, known as a blackbody radiator. A "blackbody radiator" (which is a material that exists only in theory) emits at 100%. Rough, porous materials, such as wood, paper, and powder, exhibit high emissivities ($E > 70\%$), while very shiny materials, such as stainless steel or aluminum, have low emissivities ($E < 40\%$). A mirror has the lowest emissivity—nearly 0. Conventional IR devices are designed and calibrated to theoretical blackbody conditions at a single ambient temperature; emissivity shifts must be accounted for by calibration at multiple temperatures. Accuracy can be as good as ±1%, although this is only possible with careful, repeated calibrations.

Originally, primitive optical pyrometers worked by visually comparing the color of a heated filament with that of the object to be measured. While this was a noncontact method, its disadvantages were that objects had to be hot enough to emit visible light, and human visual comparisons led to high measurement variability. Modern-day industrial radiation pyrometers measure the energy collected by a calibrated receiver electronically and work over both visible and invisible (IR) wavelengths (Carocci, 1995; Land Infrared Company, 1995).

Today, there are several types of radiation thermometers. Total radiation, or broadband, sensors measure the entire spectrum of energy emitted by the target. These require corrections for obscuring, interfering objects like smoke, as well as additional corrections for emissivity shifts. Single-wavelength, monochromatic sensors measure the intensity of radiation at one or a narrow range of wavelengths. They are accurate so long as the emissivity characteristics are well known at that wavelength. Finally, multiple-wavelength instruments can be used, and multiple-point and line-scan instruments can be used to determine an entire temperature profile over, say, a moving conveyor belt.

Not surprisingly, IR thermometers have been able to take advantage of technological advances in fiber-optic technology (Huber, 1993) and various computer-based technologies. For example, the use of flexible fiber optics allows users to locate targets that are obstructed or difficult to reach and, more important, provides immunity to electromagnetic interference (EMI). Moreover, while the first IR detectors had to be scanned mechanically, nowadays focal-plane or staring arrays (FPAs) can eliminate mechanical scanning (see Fig. 6). Using special, microprocessor-based technology, up to 78 000 detectors can be placed on one chip. Finally, computer-based statistical and image-analysis techniques have all been found to be useful in analyzing multiple-point, multiple-wavelength measurements (Finney, 1995).

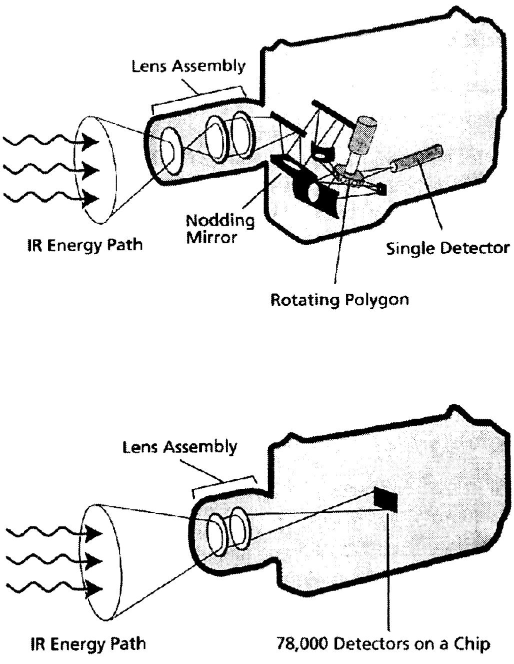

FIG. 6. Schematics for infrared thermometry cameras. Top: a mechanically scanning camera. Bottom: a staring array (focal plane) camera with 78 000 detectors on a single computer chip. (From Carocci, 1995.)

IR imaging systems produce a picture of the invisible thermal pattern of a component or process, using electronic cameras that see this thermal radiation just as a human eye sees visible light (Pompei, 1995). Such imaging systems exploit the power of multiple-point, multiple-wavelength, infrared thermography, despite its high cost. These measurement systems allow one to locate and monitor problems quickly and then to present critical decision-making information in a simple, visual form. IR imaging allows you to "see" the "hot spots" or temperature variations in complex equipment or machinery. Of course, with IR detection and imaging systems, a special type of resolution is an important specification. The resolution of the temperature of the image is a function of the sensor accuracy, the object's emissivity, the camera angle, geometry, and focus, and the distance of the camera from the object.

While the IR price per measurement is high, especially with respect to T/Cs, recent technological advances and improved manufacturing efficiencies have expanded the market for such sensors to make them cost competitive, at least on a life-cycle basis. Ultimately, the decision to use a single-point, multiple single-point, or multiple-point line scanner must be based on time, material, and energy savings, quality improvements, safety, and efficiency vs. the high sensor cost (Snell, 1995).

Typical applications of IR thermography include vacuum furnaces, induction heating, welding, and semiconductor processing. Table 7 includes a few general guidelines on choosing the right radiation thermometer (Tenney, 1988).

1.7 Signal Conditioning and Transmitters

Once a temperature signal is obtained, temperature control may be dependent on modifying or "conditioning" that signal electronically and transmitting that signal to a computer or controller. Filled thermal systems rarely use signal conditioning, but most other types do require some type of electronic manipulation. We have already introduced the concept of signal conditioning for thermocouples in discussing cold-junction compensation (Samuels, 1995). In practice,

Table 7. Guidelines for choosing the right radiation thermometer.

Material/Condition	Measuring solution
High-temperature metal, oxidizing, emittance changes	Use short wavelengths or a ratio thermometer
Glass annealing with flames	Use 4.8 to 5.2 μm wavelength
Plastic films	Use wavelength tuned to proper frequency

cold-junction compensation means that one must make electrical connections to an additional T/C junction, using the same T/C metal pair, opposite in polarity to the signal being measured. What is really measured by the electronics is the difference between the two thermocouple voltages. By convention (and for convenience), one T/C is maintained at 0 °C, so that the output voltage of the system is the output voltage of the original thermocouple. Actually, this cold-junction sensor could be a T/C, a current source, or a monolithic voltage-output temperature sensor. The errors introduced by the electronic signal conditioning as well as the accuracy of the cold-junction measurement itself may be issues with the accuracy for the desired measurement.

Inexpensive personal computers or smart microprocessors can be used with T/Cs and RTDs to improve their accuracy and precision immensely. Such devices can provide software for linearization, built-in lookup tables for popular T/C and RTD types, accurate cold-junction compensation, multiple channels for multiple temperature readings, and noise filtering to improve accuracy of repeated temperature readings. Software can be used for line-cycle averaging (filtering): several measurements per line cycle can be made to cancel positive and negative noise excursions.

In using personal computers, thermocouple leads must be appropriately shielded, and special electrical isolation techniques must be used to prevent ground-loop or common-mode errors. The computer itself must be ruggedized for its environment or properly enclosed to protect it from environmental contaminants.

Other important considerations for purchasing signal conditioners include input-to-output isolation, input protection, T/C cold-junction compensation for any and all T/C types that may be used, linearized RTD inputs, zero suppression, ambient operating range, output short-circuit protection, alarms, environmental shock, vibration, dust, military specifications, and so on. Safety can also be a concern for temperature sensors. If there is an electrical short or an electrical storm or a T/C junction "breaks," appropriate failure logic must be implemented. "Thermocouple break protection" is used to ensure that a control system will not result in a hazardous situation in response to the broken thermocouple. Fortunately, manufacturers of control and data-acquisition equipment often include hardware and software for temperature probes for safe operation, signal conditioning, and filtering (Schraff, 1995).

Transmission of the conditioned signal is also an integral part of many temperature measurements. "Smart transmitters" can be directly wired to modern transmitter units using the latest microprocessor-based digital technology to change low-level signals to high-level current signals. Use of low-cost, unshielded, twisted-pair copper wire in place of shielded cables and conduits and costly T/C extension wire often makes sense. Smart transmitters can yield overall lower total ownership cost; for, relative to conventional transmitters, they exhibit a longer lifetime, higher accuracy, and higher stability. Some smart transmitters accept many different types of sensor inputs and even conduct self-diagnostic tests to determine possible mechanical or maintenance problems (Sheng and Nodrop, 1990). Many modern temperature transmitters accept RTD and T/C signals, 4–20 mA, or digital-process variable signals on a field bus. Field bus (Berra, 1996) provides reduced wiring costs and improved accuracy. New process-control standards, such as SP88 (Sperber, 1995), should be consulted before designing the actual measurement and instrumentation systems for large-scale manufacturing plants (Craig, 1995).

Transmitters and signal conditioners may have special needs, depending on the environment they are subjected to. Some may require overvoltage protection, while others may only be useful over a limited range of environmental operating temperatures. Resistance to shock, vibration, and explosion, tightness of seal to moisture and/or dust, isolation capabilities, linearity, and the different types of sensors accepted may also be important. The turndown ratio for any device, which is the ratio of the highest value of a measurement that can be counted on to be accurate to the lowest accurate measurement value, is also an important consideration. Finally, the electronics must not be affected by stray radio-frequency signal interference—say, from passers-by carrying cellular phones or walkie-talkies. For these reasons, some people prefer the old-fashioned analog, rather than microprocessor-based, digital, transmitters.

Finally, once a signal has been conditioned and transmitted to a computer, modern-day personal computers allow users to take advantage of special data-processing aids. These include multitasking operating systems, such as Unix or Windows NT, and the dynamic data exchange (DDE) and object linking and embedding (OLE) capabilities of Windows 95 and 3.1x. Such software aids allow temperature signals from a variety of different signals to be easily compared with results from other processes and analytical measurements in real time, so that the appropriate digital filtering, signal averaging, and/or control can be applied (Wang, 1991).

1.8 Sensor Selection Criteria, Applications, and Case Studies

Temperature-measuring devices—thermocouples, RTDs, thermistors, IR thermometers, and filled thermometers—can be used for many applications, ranging from aerospace to zoology. The Works Cited and Further Reading abound in interesting and useful applications of these devices. An important goal is to use the sensor best suited to the measurement requirement of the process of interest.

In contact temperature sensing, the four most important selection criteria are response time, accuracy, size, and type of environment in which the probe will be used. Of course, these criteria often work against one another. A small probe will provide rapid response time, but may be fragile (Schraff, 1995). Also, if the probe must be protected from a harsh environment, the response time may be slowed.

Generally, stainless steel probes are a good choice for most applications, although even stainless steel may not always provide ample protection. For example, one manufacturer was using a 316 stainless steel thermowell to measure temperature of a 35% solution of caustic soda, but the thermowell had to be replaced about once every 15 days. The problem was not direct chemical corrosion, but instead, galvanic corrosion promoted by the chemically initiated electrical reaction between the thermowell and the vessel. The solution was to use a Teflon coating on one side of the thermowell.

If response time is a problem, one solution to improve response time is to make the sensor smaller. One way to do this is to use thin-film technology with platinum RTD sensors.

Noncontact sensors, while more expensive than T/Cs or RTDs, may be better suited to more difficult process-measurement requirements (Maczka, 1988). This section provides three applications of IR imaging technology: two from semiconductor manufacturing and one from the steel industry. IR imaging measurement examples are very well documented in the literature. This is likely because the IR imaging systems are so expensive that they are used mainly in applications for which less expensive T/Cs or RTDs are in some way deficient.

In many fields, heat can be a contributor to unreliability. In electronics, a key reliability factor is semiconductor junction temperature. The higher this temperature, the shorter the time to failure. When operating, a semiconductor is dissipating power and generating heat. So long as the device is generating heat, the temperature of the junction will rise in relation to the capacity of the path to conduct heat away from the device. At some point, heat flow from the device will be equal to the heat being generated, and thermal equilibrium will be reached. Thermal images can provide measurements of semiconductor case temperatures. Assuming one knows the value for thermal resistance, the junction temperatures can be determined (Walcutt, 1994).

A second and less well-recognized thermal problem occurs in manufacturing when circuit boards are reflow soldered. Today, many companies are experiencing problems with solder connections. Newer designs with their fine pitch and high component densities yield circuit boards that experience problems due to solder joint failures. This is particularly true for boards that go through reflow soldering. As in all solder processes, temperature is critical to the quality of solder connections. Not only is absolute temperature important; so is the uniformity of temperature across the board. If the thermal profile across the board is not uniform, the flux will not be cleaned, and the solder will not properly reflow. The results are inconsistent interconnect integrity and reduced reliability. Because of the high temperatures to which they are subjected and their complex structure, some boards become misshapen or warped. Others exhibit mechanical problems with components or solder connections due to thermal stresses. IR reflow ovens assume that a fairly homogeneous object is being heated, while in fact the temperatures across the board are frequently not uniform. In one application, an IR thermal image of a circuit board just removed from a reflow machine showed a large swing in temperature from minimum to maximum, even though the temperatures were expected to be uniform, since the board was just removed from the oven. Instead, the thermal image showed this board's temperatures exhibiting a ΔT of more than 70 °C. The value of seeing the whole temperature presentation on one display shows the power of thermal imaging (Williamson Corporation, 1995).

In the steel industry, noncontact, noninvasive IR measurements can save lives because they identify potentially catastrophic events before they happen. This industry uses IR cameras periodically to survey refractory in teeming ladles and gondolas that transport molten metal in steel making. Refractory, a heat-resistant ceramic metal, deteriorates over time, leading to burn-through and tons of molten metal being spilled near personnel. IR imaging can quickly and accurately determine the condition of equipment from a distance without process interruption (Carocci, 1995).

2. CONTROL

The purpose of any control system is to maintain one or more variables in a production process at a desired value. For example, keeping the temperature in an oven at 170 °C might be an important aspect of a commercial bakery. Sensors measure the temperature using one of the means described in the previous sections. The signal from the sensor is transmitted to the comparator, or error detector, within the controller. The comparator determines if there is any difference between the value measured by the sensor and the desired value. The desired value is usually referred to as the set point. Any difference between the actual value measured by the sensor and the set point is known as the error. When an error exists, the controller detects the magnitude of the error signal, makes a decision based on the error and transmits a signal to the final control device to correct the error in the controlled variable. For example, the controller may call for an increase in the flow of gas when the bakery oven temperature falls below 170 °C. In such a case, the flow of gas is the manipulated variable. The action of the controller produces a change in the manipulated variable causing a change in the temperature, the controlled variable.

Control systems are usually based on the principle of negative feedback: there is an error detected by a temperature-measuring system, and so the controller takes action to counteract that error. That is, a feedback-control loop uses the value of the error signal to make an appropriate change in the value of the manipulated variable. The new value of the controlled variable is continuously monitored by the sensor, whose signal is fed into the control system to complete the feedback loop. In this way, the control system acts continuously to maintain the controlled variable within acceptable limits.

Block diagrams (see Fig. 7) are often used to represent the actual pieces of hardware where these variables change from one form of energy or material flow to another (Shinskey, 1993). Figure 7 shows the concept of negative feedback control, indicated by inversion of sign at the summing junction on the block diagram. The input to the final control element is usually an electronic or pneumatic signal. The value of this signal determines whether the valve opens or closes. Block diagrams usually have one or more "comparators," which are used to compare two or more simultaneous electronic or pneumatic input signals. Often one input is the set point; the other may be the value of the measured variable. In the comparators,

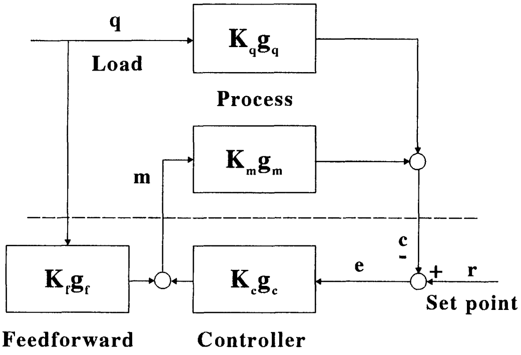

FIG. 7. A typical control block diagram, illustrating the load or disturbance, the process, the process controller, and the comparator for the set point. The *K*'s refer to gains, while the *g*'s refer to "process transfer functions" relating the variables for the load, the measurement, and the controller. (From Shinskey, 1993.)

one input is subtracted from another to determine the error. Although systems vary in complexity, they can all be represented using this simple method of connecting blocks with lines and arrows.

2.1 Standard Feedback-Control Techniques: On/off and Proportional–Integral–Derivative Controllers

On/off control is the simplest form of control, used by almost all domestic thermostats (Williams, 1995). On/off controllers are generally used either in processes that respond slowly to changes in the manipulated variable or in cases where the controlled variable can tolerate some deviation from the set point. On/off control may be used to turn on or off a furnace to keep the temperature of a house within reasonable limits. When the room gets cooler than the set-point temperature, the furnace is switched on. Once the room gets hotter than the set-point temperature, the furnace is switched off entirely. The turn-on and turn-off temperatures are deliberately made to differ by a small amount to prevent noise from switching the furnace rapidly and unnecessarily when the temperature is near the set point.

To control processes that respond quickly to changes in the manipulated variable or those that require fairly precise control of the controlled variable, it is necessary to have more than just on and off control. For example, in a continuous production process heated by steam, steam flow should be regulated by setting the control valve so that the steam flow will maintain the temperature at the set point. This means that the control valve must be set at some position between fully opened and fully closed. The control system can then make adjustments to the valve position—opening it more or less fully, to correct for variations from set point.

A proportional controller should perform better than an on/off controller, since it applies a change to the manipulated variable (e.g., a resistance heater) in proportion to the difference in temperature between the actual temperature and the set point (Williams, 1995).

The output of a proportional controller output is given by

$$O = Ke, \tag{2}$$

where the controller gain K is typically less than 1.0 and e is an appropriately normalized error signal (e usually is equal to the set point minus the measured variable). Sometimes the gain is expressed as the proportional band,

$$P = 100\%(1/K); \tag{3}$$

P (often expressed as PB) is the percentage change in controller output signal resulting from a process deviation. A 200% PB means that a 10% change in measurement signal produces a 5% change in controller output signal.

As the gain increases for a proportional controller, the system responds faster to changes in set point but becomes progressively underdamped and eventually unstable: The set point can be drastically overshot. Another problem with a proportional controller is that, even after a steady, controlled condition is established, there is some offset: The error never really reduces to zero. A proportional controller will always have an offset when working under load. This offset is $P(m - b)/100$, where P is the proportional band, m the manipulated variable, and b the output bias.

The stability and overshooting problems that arise when a proportional controller is used at high gain can be mitigated by adding a term proportional to the time derivative of the error signal:

$$O = Ke + K_d \frac{de}{dt}. \tag{4}$$

This technique is known as proportional–derivative (PD) control. The value of the damping constant, K_d, can be adjusted to achieve a critically damped response to changes in the set-point temperature.

The adjustment for derivative action is called the rate adjustment. If this adjustment is set too low, the control system will not respond quickly enough to load changes. If the rate action is too high, the response to even small changes in the controlled variable will be too great and the control system will become unstable. Instead of progressively reducing errors in the controlled variable, derivative action may actually compound them. The controller will need to be carefully tuned to prevent this from happening.

Although PD control deals neatly with the overshoot and ringing problems associated with proportional control, it does not cure the problem with the steady-state error. Fortunately it is possible to eliminate this by adding an integral term to the control function. The equation then becomes

$$O = K\left(e + K_d \frac{de}{dt} + K_i \int_0^t e\,dt\right), \tag{5}$$

where K_i, the integral gain parameter, is sometimes known as the controller reset level. The controller is known as a proportional–integral–differential, or PID, controller. The effect of the integral term is to change the manipulated variable until the time-averaged value of the temperature error is zero.

A PID controller is often called a three-mode controller. The three modes use the same error signal but each in a different way. The proportional mode uses information about the magnitude of the error. The derivative mode uses information about the rate of error change. The integral mode uses information about the average error over a specified period of time. In nonmathematical terms, the integral unit monitors the performance of the proportional unit. If it finds that there is an offset, it shifts, or resets, the proportional control action. Because of its ability to return a system to its set point, integral action is also known as reset action.

PID controllers work well, but the mathematical analysis of a PID controller is complicated since the system is third order. Unlike second-order systems, third-order systems are uncommon in physics, but the methods of control theory make analysis of them quite straightforward. By applying the so-called Routh–Hurwitz stability criterion, which is a systematic way of classifying the complex roots of the auxiliary equation for the model, one can show that, provided the integral gain is kept sufficiently small, parameter values can be found to give an acceptably damped response with the temperature error eventually tending to zero if the set point is changed by a step or linear ramp in time. Whereas derivative control should improve the system damping, integral control, especially at high gain, eliminates steady-state error at the expense of some stability (Williams, 1995).

In its raw form, integral control can be a mixed blessing: If the error $T_S - T_0$ is large for a long period—for example, after a large change in the set point or when the controller is switched on—the value of the integral term can become very large. The control action can result in overshooting or undershooting the set point and may take a long time to recover. More sophisticated controllers prevent excessive integral action, using aids like "antireset windup" usually implemented in the control software. The "windup" problem with some electronic controllers occurs because electronic controllers use capacitors for integral action, which can only store a maximum charge and thus become saturated. This saturation causes integral action to be deficient. Antireset windup ensures stability by only implementing the full integral action when the system is fairly close to equilibrium (far from saturation).

Any system that uses a resistive electrical heater to control temperature is inherently nonlinear, since an electrical heater can only generate, not absorb, heat. Thus such heaters artificially act as "integrators." When the oven temperature is higher than the set point, cooling occurs at a rate that depends on the oven and its temperature, not the controller. Dual PID controllers or special "split-range" controllers allow different heating and cooling parameter values to cope with such special conditions.

Commercial PID controllers may use parameters that do not exactly correspond to the parameters defined in this section. Values are sometimes specified in software in such a way that a long integral time constant is equivalent to a low value of K_i, whereas a long derivative time constant means a large value of K_d. The proportional gain is sometimes set by choosing a proportional band (PB), which is the fractional change in temperature that gives maximum change in the manipulated variable, so that a small number for this corresponds to a large K value. Commercial PID controllers have a variety of features; for example, some provide alarms or take special action if a temperature probe malfunctions; some provide digital, while others an analog temperature display; and most provide control for a variety of different sensor types. The commercial literature (Wahl, 1995; Anon., 1989a; Larson, 1995) is useful for obtaining a controller with the exact features and specifications required by the application of interest.

Once a controller is purchased, knowing "what buttons to push" in a three-mode, PID controller requires expertise to ensure that such a controller is tuned properly with the proper balance of control and robustness. First, the frequency domain behavior of the system should be assessed, preferably by mathematical simulation. The open- (uncontrolled) and closed-loop (controlled) frequency response for the system should be simulated, if possible. As the controller gain increases, the control system responds faster. This, of course, can cause the overshoot problem described earlier for proportional controllers. With three-mode controllers, the magnitude of the overshoots may be high. Moreover, the controller's response in time, which may be modeled as a "phase lag" between the time the disturbance takes place and the time that the controller responds, can produce a large overshoot resulting in a sharp, resonant peak. This derives from the characteristic frequency-domain response. Any additional lags in the system, for example, a nonnegligible time constant for the sensor to measure and transmit the signal, must also be accounted for in tuning to avoid overshoots or undershoots.

There are standard approaches for tuning PID controllers. In many ways, piano tuning and controller tuning are alike (St. Clair, 1991). A deep understanding of mathematics is not really required for either, but understanding *frequency* is. A piano tuner knows that the note A above middle C must be 440 Hz; other notes follow. Similarly, a controller must be tuned according to the dominant frequency of the process. This is especially true with three-mode controllers.

Ziegler and Nichols (1942) suggested the following approach to controller tuning. First, increase the controller gain until the control loop begins to cycle (Anon., 1989b). The period of the cycle is the natural period for the process. Formulas for the controller settings are based on this period and the gain that caused the cycle. In practice, this is done by placing the controller in manual and by making a small change, a step change, in the controller output. Response of the measured variable to this step change is made. After a delay, the measured variable will change, and, if the system is well behaved, it will eventually level out. Some process-variable gain will be produced, after some delay, or "dead time."

To understand dead time, imagine a freight train starting to move. All train cars are coupled. When the engine starts, the caboose does not start right away. It must wait some dead time while the other cars get going. Similarly, when the controller output moves, the controlled variable does not move immediately, but must wait for coupling elements in between to move. The output lags the true measurement, producing dead time, or the natural period of the process. Knowledge of the dead time or natural period and the gain can be used to assign the parameters of the PID controller using the methods calculations provided in the key articles (Ziegler and Nichols, 1942). The Ziegler–Nichols approach allows some overshoot, but the amplitude of the oscillation should decay rapidly, with the second peak being on the order of 25% of the first peak. So usually the Ziegler–Nichols PID parameters require some fine tuning, just as a piano does. More sophisticated tuning methods have been suggested (Gerry, 1991; Horton, 1991; Polonyi, 1989), but the simple Ziegler–Nichols tuning methods, properly applied in well-designed processes, can yield surprisingly good control. Autotuning methods are usually proprietary methods developed by commercial process-control companies, but it appears that controllers that tune themselves place themselves into an on/off control mode, then use Ziegler–Nichols tuning rules to refine the PID parameter estimates.

In the analysis of PID and related controllers, it is often useful to transform a controller from the time domain to the frequency domain. Laplace transforms and/or Fourier transforms of the time-domain control equations described here make it easier to assess the frequency response characteristics, i.e., resonant behavior or singularities. Laplace transfer-function representations, in particular, are convenient for tuning a controller to balance performance with robustness. This is very well illustrated in a recent technical article, which discusses tuning PID controllers for batch chemical reactors (Campbell, 1993).

2.2 Advanced Control Techniques: Feed-Forward and Model-Based Approaches

While feedback control is adequate for many temperature-control requirements, it has deficiencies. The biggest is that, with simple feedback control, the controller must wait for a change in the average error, current error, or error vs. time derivative before taking action. If tuning is done properly and if disturbances are relatively small and predictable, feedback control may suffice. But it certainly makes sense, whenever possible, to use knowledge of the process in order to control it. Process knowledge leads to a "proactive" control strategy, feed-forward control, in which the controller takes the appropriate action whenever there is a change in the system that one would predict to change the temperature. In other words, information is "fed forward," usually by some sort of computer-based model, to make the adjustment to control against an incoming load or disturbance.

There are many different types of models, but they can be roughly divided into three broad categories:

1. theoretical, physicochemical-based models,
2. empirical, statistically based models, and
3. heuristic or knowledge-based models.

Some models are mixtures of one or more of these general types, while others use both feed-forward and feedback elements.

Theoretical models provide profound physical insight to the process but are often the most time-consuming and difficult to develop. Process responses can be difficult to predict. For example, chemical processes are notoriously multivariable, nonlinear, nonstationary, and subject to disturbances, constraints, noise, instrument, and transport dead times. Even when a good model is developed, such models will never predict the outcome of every conceivable disturbance, and so these controllers often still require feedback elements as a "trim" for the feed-forward prediction.

Generally, theoretical-based models for control use a dynamic model (Lee and Sullivan, 1988; Rhinehart and Riggs, 1990; Wu and Dougherty, 1993):

$$\frac{d\mathbf{y}}{dt} = \mathbf{f}(\mathbf{y},\mathbf{u},\mathbf{d},\mathbf{k}), \tag{6}$$

where all variables listed are vectors. Here the transfer function **f** may be nonlinear or complicated, **y**'s are the variable(s) to be controlled, **u**'s are the manipulated variable(s), **k** is a vector of process parameters, and **d** is a vector of process disturbances.

The finite-difference approximation used by the controller is given in one dimension by

$$(y_{sp} - y_0)/\tau = f(y,u,d,k), \tag{7}$$

leading to the generic model law, expressed as

$$f(y,u,d,k) + K_1(y_0 - y_{sp}) + K_2\int_0^t (y_0 - y_{sp})dt = 0, \tag{8}$$

where *sp* stands for set point for *y*. The control parameters K_1 and K_2 are related to the parameters used in a PI controller, the proportional gain and the integral action, respectively. Model-based controllers should be implemented using on-line computers and can be updated periodically using on-line process data to keep the model tracking the process closely. While the controller looks very much like a PI controller, this process model has the advantage that it can at least approximately predict the process's response to the actions taken by the controller, over at least a short time. The better the model, the more accurate the prediction.

In internal model control (IMC), the difference between the model output and the process value serves as the feedback signal to the IMC controller. The transfer function of the IMC controller is just a single parameter, known as the filter time constant (Chia and Lefkowitz, 1991; Studebaker, 1995). This time constant "filters" the model output values in real time to match the real-time, measured process values reasonably closely. With just this one parameter, the IMC controller is relatively straightforward to tune to get a good balance between model prediction and performance and stability or robustness as conditions change.

Statistically based models use actual process data to predict a process dynamic model, which, in turn, can be used to generate a statistically based controller. Process data, of course, is correlated in time, so that the model generated is not a simple regression model, but instead, a time-series model. Often, a process that is in reasonably good control is "perturbed" from its steady state, either intentionally or unintentionally, by making deliberate changes in the manipulated variable u. Then, a statistically based transfer function model is constructed to predict the effect of a change in u on the control variable y. There may be one or more process "gains," and several significant delays or dead times, some short and some long, but all can be expressed as time constants or critical frequencies. Often, the statistically based models are relatively simple, like first order plus dead time. Such a structure may suggest the structure of the underlying physical model of the process.

Once a transfer function is known, the remaining "noise" (or deviations of the process from the model) also usually has a time-series structure; that is, the noise is often autocorrelated in time as well. By examining both the transfer function and the noise model, one can, using well-developed, statistically based analysis, construct rigorous, semiempirical controllers. MacGregor and others (MacGregor, 1972; Box and Jenkins, 1976; Dougherty *et al.*, 1989) have developed the mathematical equations for complex, multivariate, nonlinear models and have shown that such controllers developed from these equations can perform well but still be robust and stable. Dougherty *et al.* (1989) used a statistical, time-series–based approach to develop a controller, and then they approximated that statistically based controller as a PID so that simple control instrumentation hardware could be used to implement it.

Finally, "heuristic" or knowledge-based models can also be used in modern-day control schemes. Such controllers may involve a series of "rules" preset by "experts," or, alternatively, use directed "process learning." There are many approaches to such models. Almost every digital control system involves computer programs that involve rules developed by process "experts," and so expert system models are probably the most common knowledge-based models around. On the other hand, neural networks are being used in the control of very complex, highly nonlinear, multivariate systems. These, however, require large training sets for "process learning." Finally, "fuzzy logic" is now being used in "smart instruments" for control (George, 1996; Abdelrahman, 1990). Depending on the circumstances and a set of prespecified rules, fuzzy logic controllers may take one or more of several possible courses of action to maintain a good, stable robust process that remains under control. There are no "hard and fast" rules to follow but very often a "fuzzy" solution to handle all the "gray areas" characterizing complex systems.

2.3 Applications: Two Very Different Temperature-Control Approaches

There are many temperature-control applications: the Further Reading and Works Cited abound with them. However, this section outlines just two applications for the purposes of reinforcing the concepts introduced in Secs. 2.1 and 2.2.

The first application is for control of a jacketed, batch, industrial chemical reactor (Beatty, 1988; Verhaegen, 1991). Jacketed reactors are commonly used in chemical, polymer, and fermentation processes (see Fig. 8 for a typical control setup for a fermentation reactor). Most jacketed reactors are controlled using a cascade control scheme (Fig. 9). Control is called "cascade" because one controller cascades into the next; one feed-

FIG. 9. Schematic for cascade control of a jacketed reactor. The temperature of both the batch reactor and its jacket are measured, and the signals transmitted to control valves regulating steam and cold water. Steam is added to a heat exchanger to increase the temperature, if necessary, while cold water is added to the jacket to reduce the temperature. Regulating the jacket temperature, by cascade control, regulates the batch temperature in a more stable fashion. (From Shinskey, 1993.)

back loop is "nested" inside another. In short, the process being controlled is split into two parts, and an intermediate variable for the inner loop is chosen, such as the jacket pressure or jacket outlet temperature. In cascade control, there is frequent manipulation of the set point of one controller by another; a secondary or so-called "slave" controller is responsive to the output of the primary or "master" controller.

The main reason that cascade control is used to control the temperature of large, industrial batch reactors is that these temperatures generally move very slowly in response to disturbances, which tend to be very frequent. The batch temperature is, of course, the primary cascade variable. But the choice of the secondary variable is key. Often, it is the position of a valve to let refrigerated water into the jacket. To summarize, in cascade temperature control, the temperature of the reactor (the variable that is most important to control) varies slowly with a very long time constant. When this reactor is cooled by a jacket, the jacket temperature (representing the secondary control "loop") moves more quickly in response to disturbances and generally exhibits a shorter time constant.

There are some "rules of thumb," i.e., a knowledge-based system, for determining when to use cascade control. Basically, when a number of various disturbances might be expected and overall process dynamics are slow, application of cascade should be considered. The following should be considered carefully in determining whether or not to use cascade control:

1. when a process reacts very slowly to a change in the valve position;
2. when the process value (i.e., the temperature) drifts around set point;
3. if process changes appear as disturbances on measured value (i.e., temperature);
4. if one or more variables (for example, jacket temperature or pressure) can be directly related to the measured set-point temperature; and/or
5. when, with a change of set point, quick parallel tracking between recorded and desired value is required with minimum overshoot.

Once a cascade system has been designed and is starting to work, there are some additional rules of thumb to ensure that the cascade controller works well:

1. the secondary variable should receive the maximum disturbances (there will be less chance to disturb the primary control variable, whose trajectory will move smoothly and stably toward the set point, with minimal overshoot);
2. the secondary loop must include "worst" disturbances to be expected;
3. there must be quick reaction to each change (i.e., the time constant for the secondary scale should be one fifth (i.e., faster than) that of the primary scale, so that it can rapidly respond to disturbances, with the primary variable responding more slowly and thus remaining stable);
4. the secondary controlled variable must have direct influence on the primary (e.g., a change in steam supply pressure should affect reboiler temperature);
5. there should be a directly proportional relation between the quantities in the primary and secondary loops; for example, a change in, say, the jacket temperature, the secondary variable, should be related proportionally to a change in the reactor temperature, the primary variable; and finally,
6. the variables should be linearized where possible by the use of appropriate variable transformations.

Advantages of cascade temperature control include these:

1. It reduces deviations around set point (i.e., drifting).
2. The system reacts faster.
3. The primary reaches a nearly constant value within a few time cycles.

Alarms can be made using the secondary loop, which allows for early action to be taken to prevent damages and disturbances from unnecessarily affecting the most important variable, the temperature of the large batch reactor, in the primary control loop.

While cascade control requires an analysis based on theoretical principles and statistical data, our second example illustrates a "knowledge-based" approach. Recently, commercial products have been introduced that achieve precision temperature and humidity control using fuzzy logic (Liebert Corporation, 1992; see also THEORY AND APPLICATIONS OF FUZZY LOGIC; Brubaken, 1992). This article does not endorse a particular product, but describing this particular product should help us understand some of the newer, knowledge-based approaches now being used in process-control applications.

Control of the environment for large computing systems is often a far greater challenge than for rooms inhabited by people. Not only do the systems themselves generate heat, but they are often specified by their manufacturers to be maintained in as little as a ±0.5 °C range. Humidity control is also a challenge, since corrosion rates and jamming of associated mechanical systems increases at high humidity levels, while static discharge is promoted at low levels. The humidity set point specified in this application is 50% relative humidity; but the maximum allowable change in relative humidity is only ±3% within 1 h.

In addition, the design of a precision environmental control system also faces nonlinearities, caused by such system behavior as air-flow delay and dead times, uneven airflow distribution patterns, and duct-work layouts. Uncertainties in system parameters are often present—for example, room size and shape, location of heat-producing equipment, thermal mass of equipment and walls, and amount and timing of external air introduction.

Recognizing these challenges, a control system was designed with the following objectives in mind:

1. precision temperature and humidity control;
2. minimization of cycling times (i.e., the opening and closing of the damper and turning on and off the compressor), thereby increasing reliability and component life, and also resulting in increased energy efficiency; and
3. straightforward and therefore inexpensive control electronics.

A fuzzy logic approach (Liebert Corporation, 1992; Brubaker, 1992) was investigated and ultimately implemented to achieve precise temperature control using relatively simple hardware. The actual controller consists of six fuzzy inputs, three fuzzy outputs, and 144 principles (rules). This particular control system runs on a small microprocessor; it is relatively easy to run, and new rules can be added.

Fuzzy input variables used in this system are the temperature relative to a set point, the rate of temperature change, the humidity relative to a set point, the rate of humidity change, and two proprietary variables associated with the action of the controllers.

Fuzzy outputs control the amount of cooling, the amount of dehumidification, and heat. Unlike conventional controllers, outputs can also be treated as fed-back input variables, while time delays are treated as fuzzy outputs as well. Each fuzzy variable is assigned seven membership functions as values—for example, Large Negative, Medium Negative, Small Negative, Near Zero, Small Positive, etc. Ranges for these membership functions are proprietary.

With this expert system consisting of 144 principles, more elaborate approaches to control were not necessary. Inputs are sampled, the principle base is queried, and outputs are updated once every second. The "long" intersample delay allows a simple eight-bit microprocessor to implement this rather large fuzzy system.

Relative to on/off control, fuzzy logic greatly reduces the number of system cycles, thereby significantly reducing wear on the damper. Moreover, with the rules set up the way they are, paradoxically, the outdoor ambient temperature actually assists (rather than interfering with) internal temperature control.

The control engineers wrote a PC-based simulator to test the fuzzy design under simulation prior to committing it to hardware. Their simulations and tests led them to the conclusion that fuzzy logic is able to control temperature and humidity precisely in rooms having uncertain and nonlinear characteristics. Moreover, installation includes no tuning procedure: The same set of principles evidently applies in many similar applications.

ACKNOWLEDGMENTS

The author would like to thank the Rohm and Haas Company for permission to publish this article. In addition, the author would like to thank Ed Sioma and Dick Wu for many helpful discussions on temperature control; and Greg Shinskey, Marcia Katz, Bruce Carocci, Steve Lorbert, and Jim Pike—those authors who have granted me permission to use their figures.

GLOSSARY

Accuracy: The closeness of agreement between an observed value and the true value.

Antireset Windup: Feature in a three-mode PID controller that prevents the integral circuit from functioning when the temperature is outside the proportional band.

Block Diagram: A diagram of a process-control system to show the relationships of all the loop elements.

Calibration: The procedure of comparing a particular instrument with either a primary standard or a secondary standard with a higher accuracy than the instrument to be calibrated.

Cascade Control: Control in which the output of one controller is the set point for another.

Cold-Junction Compensation: Use of a reference thermocouple, usually held at 0 °C (cold), to compare with to improve thermocouple accuracy.

Drift: An undesired change in the output–input relationship over time.

Emissivity: Ratio of energy emitted by an object to the energy emitted by a blackbody at the same temperature. Emissivity depends on the material and surface texture.

Feedback Control: Type of control in which a measured variable is compared to its desired value to produce a signal that reduces the magnitude of the error.

Feed-Forward Control: Type of control in which the control system anticipates the effect of measured disturbances and compensates for them.

Filled Thermal Systems: The method of measuring temperature that involves a filled system whose characteristics change with temperature.

Fuzzy Logic: Simple, intuitive concept invented by L. Zadeh in 1965 (George, 1996) that involves "membership" in a group as the basis for basic logic, action, and control. Membership in a group or several groups may be fractional or "fuzzy."

IR Sensor: A measurement system that examines the change in radiation power density to get a measure of the temperature.

PID Control: Feedback-control method that minimizes the error by making changes in a manipulated variable according to the current error (proportional term), the average error over a specified amount of time (integral term), and the rate of change of error in time (derivative term).

Radiation Thermometer: Method of measuring temperature that involves emission of electromagnetic radiation from a targeted source.

Repeatability: The closeness of agreement among a number of consecutive measurements of the output for the same value of the input under the same operating conditions.

Resistance Thermometer: Method of measuring temperature that uses the resistance developed across a metal. May be a thermistor or an RTD.

Signal Conditioning: Operations done on a measurement to improve the accuracy of the measurement either by filtering (taking several measurements over a short period of time), linearization, or calibrating against a reference measurement. Signal conditioning is usually done using a microprocessor or a personal computer.

Thermocouple: A device for measuring temperature, based on the junction of two dissimilar metals, which has a voltage output proportional to the difference in temperature between the hot junction and the lead wires (cold junction).

Thermowell: Closed-end tube designed to protect temperature sensors from harsh or corrosive environments, high pressures, and flows.

Transmitter: A device that responds to a measured variable, converting it to a standardized signal that is a function only of the measured variable.

INTRODUCTION

The application of electrical test equipment encompasses several areas. These include the measurement of properties and values of the components that make up the circuit, levels and characteristics of the potential and current sources used to power the circuit, the level and characteristics of the input and output signals associated with the circuit, the levels and characteristics of the noise present in the system, and the overall system characteristics. Table 1 provides an overview of the major areas of electrical testing, specific areas of interest by category, types of measurements required, the applicable types of electrical test equipment, and auxiliary equipment that may be required.

Electrical test equipment has undergone revolutionary changes during the past several years. Advances in microcircuitry and embedded-microprocessor technology have had a very significant impact on both the industry and those who must make electrical test measurements. Such advances have brought "field-grade" equipment almost to the level previously considered as belonging to laboratory-grade calibration equipment.

Most electrical test equipment utilizes the increased analysis and diagnostic capability provided by embedded computer technology. This provides the ability to perform detailed analysis as measurements are being made. The disadvantage is that the user must sometimes spend considerable time in understanding the capabilities that are available and how best to utilize them. This increased sophistication and capabilities of modern electrical test equipment, while providing

greatly increased functionality, does not relieve the user from having a basic understanding of electrical measurements, proper choice of equipment, proper interpretation of the results, and proper safety precautions to be followed while making such measurements. It is time well spent and results in the optimal use of the instrument and ultimately in time savings and more useful measurements.

Many of the manufacturers of electrical test equipment such as Tektronix, Hewlett Packard, and Fluke, to name just a few, provide excellent literature describing not only the latest in electrical test equipment but also literature and application notes that describe the latest measurement techniques and methods for performing many types of electrical measurements. Much of this literature is provided free of charge or at nominal cost.

1. FUNDAMENTAL CIRCUIT

All electric circuits possess common characteristics. The circuit is composed of some number of components, it must be powered from some source, the power generally must be converted and conditioned, it operates on and or produces some form of signal, it is subject to and produces electrical noise, and these circuits are combined to form complex systems. Electrical test equipment is available and used to make measurements in each of these areas. For reference, each area is illustrated in Fig. 1.

The *electrical circuit* is powered by the *power source* through the *power supply.* The electrical circuit may be a complex electronic circuit involving semiconductors, microwave devices, logic elements, electric heating equipment, or electric motors or other electromechanical devices. The input signal may be a complex communications signal, a signal from a process sensor, logic input from a preceding stage of a computational system, the set point for a process control function, or a simple on-off switch. The output signal may be a microwave signal, a current to a heating unit, a command to a process actuator such as a solenoid valve or motor, or a low-level logic pulse. Each of these elements has need to be accurately measured to ensure that the circuit is performing as designed and required. That is the function of electrical test equipment.

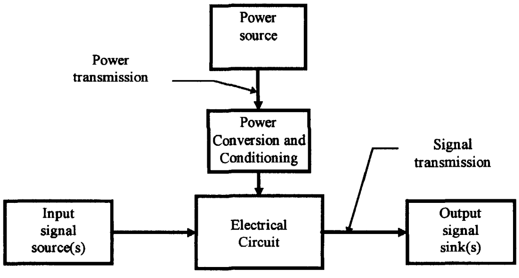

FIG. 1. Basic electric circuit.

The power source may provide direct current or alternating current, and virtually any voltage level and polarity as a function of time. The power supply may simply filter the power, or it may transform, rectify, filter, and/or regulate the power. The electrical circuit may perform any number of functions from simple to very complex. The signal source and sink may also be very simple or complex. All of these elements have common attributes: they may each require measurement of voltage, current, power, noise, frequency, ac and dc component content, phase, resistance, and impedance. The current levels may vary from a few milliamperes to thousands of amperes; the voltage levels may likewise extend over a broad range.

2. COMPONENT MEASUREMENTS

Accurate measurement and characterization of the components that make up a circuit is sometimes required to understand the performance of the circuit. Electrical test equipment has been designed for application to each specific category of component.

2.1 Passive Components

2.1.1 Resistance, Capacitance, Inductance, and Impedance Measurement Resistance, capacitance, and inductance are properties associated with all circuit elements to varying degrees. Impedance is the term applied to the combined effects of resistance, capacitance, and inductance and is frequency dependent. It can be the result of combined effects of discrete components such as resistors, capacitors, and inductors in a circuit or distributed effects such as in cables, wiring, and circuit boards.

2.1.2 Multimeters Digital multimeters (DMMs) offer a low-cost, generally rugged, method of making voltage, current, and resistance measurements over wide ranges and test conditions. Such instruments are well suited to everyday laboratory and field measurements and have generally replaced bridges for making even the most precise electrical measurements in the laboratory.

2.1.3 *LCR* Meters The *LCR* (inductance, resistance, and capacitance) meter is used for high-accuracy measurement of passive components. In addition to making simple resistance, capacitance, and inductance measurements, these meters may also be used to make measurements of other parameters such as admittance, phase angle, reactance, conductance, Q for inductors, dissipation factor, and Equivalent Series Resistance (ESR) for capacitors. These meters are typically capable of measuring over the range of 0.01 mΩ to 10^{16} Ω for resistance, 0.001 pF to several hundred microfarad for capacitance, and 0.01 nH to 100 kH for inductance (depending on the particular instrument). Specialty instruments may also be available for measurement ranges that exceed those cited. Many of these instruments also provide the ability to apply bias currents to inductors, bias voltages to capacitors, and rf to components as they are being tested.

Special adapters are also available that allow the measurement of various-component physical configurations such as surface-mount devices, the application of high bias voltages, high bias currents, and other special-purpose applications. In addition to the test and measurement of individual, discrete components, special configurations of these meters may be used for materials testing (e.g., circuit boards) and dielectric testing.

2.1.4 Impedance Analyzers Impedance analyzers, in addition to providing the measurement capabilities of *LCR* meters, also provide the ability to measure impedance, phase, and transmission parameters. These instruments generally cover a wider frequency range, and they have the ability to sweep over a selected frequency range.

2.2 Active Components

The measurement of active components such as transistors, diodes, and related components involves "driving" the component with a prescribed test condition and measuring the response of the device. For example, in the case of a diode, parameters of importance include forward voltage drop at a specific current or over a range of currents, reverse breakdown voltage, reverse leakage current at a specified voltage, reverse recovery time, and other properties based on the application. In testing forward voltage drop, the device is subjected to a specific level of current in the forward or conduction direction, and the voltage drop across the diode is measured. In some cases, the forward current may be of such magnitude that the diode would not survive if the current was applied continuously. The current must therefore be pulsed through the diode and a measurement taken within a relatively short time. Such measurements require generally more complex test equipment than that required for passive-component measurement.

2.2.1 Semiconductor Measurement Systems Semiconductor measurement systems provide the ability to expose discrete semiconductor devices to desired test conditions and measure the response of the device. These instruments may be used to measure dc gain, leakage current, and small-signal parameters in both pulsed and steady-state conditions. An example of such a test on a bipolar transistor would be the application of a specific base current level, swept over a predefined range, and the measurement of the corresponding collector current. In the case of a field-effect transistor, the gate voltage would be swept over a predefined range and the source current measured and plotted as a function of the gate voltage. The advantage of such an instrument lies in the ability to perform routine semiconductor measurements, under steady-state and pulsed conditions, without the need to fabricate and test custom test fixtures.

2.2.2 Integrated-Circuit Testers These systems are considerably more complex than the instruments used to measure individual components but provide the ability to measure and assess the performance of entire analog and digital integrated circuits. These test systems are programmable and can measure, store, display, and analyze entire circuits. They provide for the application of a complex set of excitation signals and conditions and the ability to record and analyze the output signals.

3. POWER SOURCES

All circuits require some form of power source. The source may be solar cells, batteries, line voltage, or any number of other such sources. Irrespective of the source, it must be capable of providing the required voltage and current level required by the circuit. It must produce very little electrical noise and must possess the required degree of regulation.

3.1 Voltage Sources

While some circuits may require a constant-current source, the most commonly used source provides a constant voltage to power the circuit. These are generally regulated to some degree but may also be completely unregulated. In the case of unregulated voltage sources, the output voltage level of the source will vary as a function of the load and the line supply voltage. In the case of regulated sources, the output voltage is held constant through the use of a sensing and feedback circuit. This feedback circuit utilizes active circuit components, e.g., regulators and error amplifiers, to maintain the desired output voltage at the desired level relatively independent of load and line voltage variations.

3.1.1 ac Voltage Sources The most common source of ac is that supplied through the 60- and 50-Hz commercial power grids. The power-line voltage is generally not used directly except for lighting and powering motors. In most electronic applications the power is transformed to a lower voltage, rectified, filtered, and regulated before being used to power a circuit. However, some applications may require an ac source that provides voltage at a specific frequency.

3.1.1.1 ac Power Supplies. High-power, single-phase and multi-phase, fixed- and variable-frequency ac voltage sources are available. These supplies typically operate from line power and rectify the line ac voltage to provide a source of dc. The dc power is then used to power oscillator and power-amplifier circuits, which in turn provide the ac power at the desired frequency and voltage level.

3.1.2 dc Voltage Sources

3.1.2.1 Constant-Voltage Supplies. Constant-voltage supplies, just as their name indicates, provide a source of constant voltage independent of the level of current required (within prescribed limits). Circuitry within the supply converts the ac line voltage into dc voltage through the use of voltage transformation and rectification. The resulting dc voltage is further filtered to reduce ripple effects that remain following the rectification process. The filtered dc voltage is then applied to voltage-regulating circuitry. The purpose of the regulating circuitry is to maintain the output voltage of the supply as close to the preset voltage as is reasonably possible, with the cost of the supply generally proportional to the degree of filtering and regulation required. The degree of regulation is specified for each particular type of supply and is a function of both the load current and the line supply voltage. The two primary types of regulation used are series/parallel or *linear* regulation and switching regulation.

In series regulation, a series pass element is placed between the filter stage of the supply and the output terminals. The arrangement of a typical circuit is shown in Fig. 2. A feedback circuit provides the series pass element with an appropriate regulating signal that is inversely proportional to the output voltage and is compared with the preset or desired reference voltage. The primary disadvantage of the linear regulating type power supply is its inefficiency. Since the supply operates from a fixed "up-stream" voltage source, i.e., the filter circuit, the only way in which it can maintain the desired output voltage is to drop voltage across the regulating element. This corresponds to power dissipation within the supply and becomes worse as more current is required by

the load. The relative advantage of the linear supply is its simplicity and lower cost.

The more efficient method of regulating the output of a constant voltage supply is the *switching* regulator. Using the relationship $Q \cong CV$, or, rearranging, $V \cong Q/C$, one can see that it is possible to control the voltage across a capacitor by varying the quantity of charge present on the capacitor. This is the fundamental operating principle of the switching regulator. A high-frequency pulse stream is supplied to a capacitor through a *charge-pump* circuit. The amount of charge deposited on the capacitor is a function of the desired output voltage level. As the output voltage drops, the frequency of the charging circuit increases to replenish the charge on the capacitor, thereby increasing the voltage across the capacitor. The major advantage of this type of supply is its higher efficiency and lighter weight. A key concern in the use of this type supply, particularly with digital electronic circuits, is the level of ripple on the output voltage and the level of output regulation. This ripple is an artifact of the charging circuit and can have adverse effects on digital circuit applications, which may be particularly sensitive to switching transients. Significant effort is made to filter out such noise.

Almost all laboratory or bench-top power supplies incorporate some form of output-current limit protection including short-circuit protection. Some supplies are equipped with a variable current-limit capability that allows the user to preset the maximum allowable current available. This can prevent damage to test or experimental circuits during development. Other types of supplies are equipped with a simpler crow-bar circuit, which operates by "crow-barring" the input to the supply to zero when the output current exceeds the maximum limit. Both of these methods are aimed at preventing too much current from flowing through the load, thereby minimizing damage to the load and also to the supply. The variable current-limit supply is by far the more popular and functional since it allows the user to set the level at the most desirable level.

3.1.2.2 Constant-Current Supplies. In some applications it is necessary to maintain the current at a constant value and allow the voltage to adjust as necessary to maintain the desired current. Such supplies are referred to as *constant current* supplies. The current is maintained at a constant level by allowing the applied voltage to vary in proportion to the load. The voltage is referred to as the compliance voltage, and the preset current level may be maintained as long as the compliance voltage range is not exceeded. This is analogous to the maximum allowable current output from a constant voltage supply.

4. POWER-SUPPLY MEASUREMENTS

Most commercial power supplies are equipped with some form of meter or display to allow monitoring of output conditions. If such features are not provided, the output may obviously be measured or monitored using any of the equipment referenced in the signal-source measurement section. In addition to voltage and current measurements, it may be desirable to measure the output ripple, output power, or output noise or to observe the output wave form of a variable-frequency ac supply.

In assessing the quality of the power used for an application, it may be necessary to utilize any or all the instruments listed in the following sections.

4.1 Multimeters

Aside from dedicated equipment, the analog or digital multimeter is very useful for measuring the output voltage and current levels of power supplies. They are relatively low in cost and designed for portability.

The multipurpose meter or multimeter has probably been the most used, general-purpose piece of electrical test equipment on account of its handheld portability, simplicity, and application to the most common types of field measurements. It provides the ability to measure ac and dc voltages over the ranges from a few volts to 600 V, dc currents from a few milliamperes to typically 10 A, and dc resistance from milliohms (in some cases) to several megohms. The use of the field-effect transistor input stage provides even the analog multimeter with a relatively high input impedance.

4.1.1 Analog In its simplest form, the analog volt-ohmmeter (VOM) consists of an analog current-meter movement with appropriate current-limiting resistor combinations to provide several voltage ranges, several shunt-resistor configurations to provide various current ranges, and a battery circuit and resistors to provide a resistance measurement capability.

4.1.2 Digital The digital implementation of the traditional multimeter contains an analog-to-digital sampling circuit and digital display in place of the analog-meter portion of the conventional multimeter. The display is usually a liquid-crystal display unit to conserve power. A drawback of the digital multimeter is the inconsistency of readings due to the sampling of the analog-to-digital circuit, particularly on a noisy signal. While the analog meter mechanically "integrates" signal variations, the digital meter is very capable of sampling and displaying instantaneous signal values. In a noisy environment, this may prove to be very confusing as the display "hops" from one value to another. To help overcome this problem, some digital meters are equipped with an internal integrating circuit that filters out such instantaneous variations. A key advantage of digital instrumentation is its ability to autorange in response to the voltage being measured. In the simple analog meter-based instrument there is no provision to detect and adjust the meter's range, whereas in the digital version, it is possible for the more sophisticated input circuitry to detect the magnitude (and polarity in the case of dc voltages and currents) of the input voltage and adjust the display to the appropriate range.

4.2 Power-Line Monitors

The quality of the commercial power is generally assumed to be adequate for most applications. It is generally assumed that the line voltage is 120 VAC, 60 (or 50) Hz, that the power is clean (i.e., no noise, voltage "spikes," transients, etc.). This is generally not the case. Power-line monitors provide a means of measuring and recording fluctuations and transients on power lines. The units also detect and record sags and surges in line voltage, variations in frequency, and short-duration events such as spikes that occur on the line. They are usually equipped with an integral strip-chart printer and can be programmed to print results on demand or to print findings automatically at preset intervals. Transient events are generally reported as they occur, and variations in line frequency and voltage are generally reported at preset intervals. Multiphase units are also available, which record phase-to-phase information such as voltage differences. These instruments can be extremely useful when trying to determine the cause of intermittent problems in equipment when all other avenues have been explored.

4.3 Power Measurements

Power-measurement equipment is required when it is necessary to monitor ac input power to power-conversion equipment as well as to measure the output power of such equipment. Depending upon the application or requirement, a conventional watt meter may be sufficient for most ac power-source measurements; or, for more general applications, e.g., high-voltage, high-current, or floating measurements, a combination of current probes, voltage probes, and interface equipment to the oscilloscope can provide a very versatile power-measurement system.

4.3.1 Electronic Watt Meters Electronic watt meters are used to measure power consumption in many power-source applications. Conventional watt meters were based upon the interaction of the voltage and current within a mechanical meter arrangement. Electronic watt meters utilize electronic circuitry to determine instantaneous power, peak power, and average power, and to record power consumption as a function of time (kW-h).

4.4 Clamp-On ac Ammeters

These devices provide the ability to measure ac currents quickly, primarily in power sources. The meter is equipped with a pair of "jaws" that are opened, placed around the conductor in which the current of interest is flowing, then released. The jaws of the instrument couple to the magnetic flux encircling the conductor and transform this into a measure of the current flowing in the conductor. The meters are also equipped with a voltmeter capability, which allows the voltage to be measured with the same instrument (although not simultaneously). This provides a convenient means of determining not only the current but also the voltage and therefore the power in a power-source circuit. Since the instrument measures rms voltage and current, and is incapable of measuring the phase angle between the voltage and current, it is only useful in the determination of rms power and not reactive power.

4.5 Oscilloscopes

Although used primarily for observing signals into and out of circuits, oscilloscopes can be very useful for observing output levels, noise, and ripple in power-supply applications. When used to observe power-line input noise or voltage levels, care should be taken to avoid shorting the line to ground through the oscilloscope ground.

4.6 Spectrum Analyzers

Spectrum analyzers, like oscilloscopes, are primarily intended for observing signal information. However, spectrum analyzers can prove extremely useful in assessing the quality of input and output power from power supplies and sources.

5. SIGNAL SOURCES

In addition to the power supplies to power the circuit, some form of input signal is required for the circuit during normal operation or for testing. Several types of signal sources are available based on the type, frequency, magnitude, accuracy, and stability of the required signal.

5.1 Sweep and Function Generators

Sweep and function generators provide the ability to vary the output frequency or voltage function in a specified manner. In the case of the sweep generator, the user may select a start and stop frequency and initiate a sweep over the specified range. These instruments are generally used in signal analysis in radio-frequency (rf) and microwave applications.

Function generators produce a varied range of voltage values as a function of time. These are generally fixed wave forms and include sine, triangular, sawtooth, and square-wave voltage signals. Lower-priced versions of these instruments are designed for general use, while more expensive and therefore more precise instruments are available (see also Sec 5.2).

5.2 Arbitrary-Function Generators

The more common function generators are limited to generating single-pulse functions or relatively simple repetitive functions (triangle, sine, and sawtooth). In some applications it is necessary to produce more complex repetitive or nonrepetitive voltages as a function of time. Signals such as those obtained from mechanically vibrating systems, radar echoes, "random" nuclear decay events, and similar naturally occurring sources are not usually composed of simple functions but rather consist of complex combinations of many functions or randomly distributed pulses.

Where these signals must be reproduced or simulated, an arbitrary-function generator (AFG) can prove to be indispensable. An arbitrary-function generator is capable of generating virtually any wave form that can be programmed into the system, the only limitation being the required resolution and the amount of memory available in the AFG.

The AFG basically consists of a memory unit, a clocking unit, a counter unit, and a digital-to-analog conversion unit.

The wave form to be generated is stored in the AFG memory in digital form (usually 8 bit). Each memory location is then "clocked out" to the digital-to-analog conversion (DAC) circuitry. The DAC operation converts the signal to an analog representation of the corresponding signal. A block diagram of an AFG is shown in Fig. 3.

The wave form is stored in the random access memory (RAM) through the use of programming software in the form of 8-bit bytes (some systems allow 16-bit words). Following the programming of the memory, the oscillator is allowed to increment a counting circuit. The output of the counting circuit is used as the address pointer to the RAM. The content of each memory location of the RAM is then transferred to the DAC where it is converted to analog form. Essentially any wave form that can be defined as a series of digital bytes can be reproduced by the AFG.

Wave forms are programmed into the unit through several mechanisms. They may be generated by a library of mathematical functions, interpolation, graphic or tabular entry of instantaneous level, or tabular entry of the desired wave form in digital format. Wave forms may also be combined to produce even more complex functions. The system may also be programmed to produce noise functions.

Software is provided to allow the user to interact more easily with the system especially in the definition and generation of highly complex wave forms.

Key considerations in selecting an AFG include the number of output channels required, memory depth, output resolution, the need for simultaneous analog and digital outputs, wave-form entry modes, and peak-to-peak output voltage range.

These generators are capable of producing signals that range in frequency from dc to several megahertz. They can also provide a ± dc offset. The peak-to-peak output voltage capability varies from model to model but 10 V is common, with some units providing as little as 2 V and as much as 20 V. If higher or lower amplitudes are required, appropriate amplifiers or attenuators can be used to adjust the level. Single- and dual-channel configurations are available with both analog and digital data being available simultaneously. Essentially all units can be remotely programmed using the General Purpose Instrument Bus (GPIB) protocol (see Sec. 13; and BUS SYSTEMS AND COMPUTER INTERFACING).

6. SIGNAL MEASUREMENT EQUIPMENT

6.1 Oscilloscopes

Oscilloscopes are used to observe voltage and current wave forms directly in the time domain. They offer the advantage of observation of high-frequency and complex signals.

6.1.1 Types of Oscilloscopes There are two basic classes of oscilloscopes: analog and digital. Each is designed for specific applications with requirements vs cost being a principal consideration. Most general-purpose oscilloscopes are based on analog designs and are used for measurement and monitoring of commonly encountered conditions such as general circuit design and

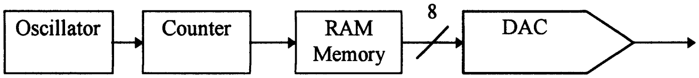

FIG. 3. Block diagram of arbitrary-function generator.

checkout; others are designed for observance and detection of specific high-speed phenomena or events. These include relatively simple analog scopes, analog storage scopes, digital scopes, digital storage scopes, and other more specialized scopes. See OSCILLOSCOPES ANALOG AND DIGITAL.

6.1.1.1 Analog Oscilloscopes. Analog oscilloscopes consist basically of input amplification circuitry, timing electronics, and support circuitry. The signal to be measured is scaled and displayed directly on the screen. The general-purpose analog scope is valued for its simplicity and low cost. It is used in circuit design activities, general troubleshooting, and other "everyday" activities. Analog storage scopes provide the ability to store the signal trace temporarily for longer viewing. It is useful for viewing single, high-speed events. The cathode-ray tube (CRT) uses a high-persistence phosphor that is capable of holding the image longer. This allows the image to be viewed longer and to be photographed easier.

6.1.1.2 Digital Oscilloscopes. The digital oscilloscope is replacing the analog scope in many areas because of its increased flexibility and decreasing cost. The digital oscilloscope utilizes a front end similar to that of an analog oscilloscope; there is an attenuator and a preamplifier section to condition the input signal as in the analog oscilloscope. However, that is where the similarity ends. In a digital oscilloscope, there is an analog-to-digital converter (ADC) immediately following the preamplifier. The ADC converts the incoming signal to its digital representation so that it may be processed, analyzed, and displayed. The high degree of accuracy and the relative complexity of the ADC generally results in a higher cost for that section. In lower-cost multichannel oscilloscopes there is a single ADC section that is shared between each of the input channels. Once the conversion has been accomplished, the digital data are stored and displayed. In the case of the digital storage scope the advantage is that the screen may be refreshed with the digital data by merely recalling it from memory.

Digital oscilloscopes also offer several types of mathematical functions. These include sum and difference of two channels, and the ability to compute and display histograms. A very powerful feature is the ability to transform the sampled wave form into the frequency domain and display the result. An example of this type of display is shown in Fig. 4.

There are two types of digital oscilloscopes: real-time (RT) and equivalent-time sampled (ETS). Those that use real-time, direct high-speed sampling circuits to capture the wave form provide a much more accurate representation of randomly occurring events such as glitches. ETS-based oscilloscopes acquire a number of samples of a wave form over several periods and "build up" the wave form that is then displayed. The ETS oscilloscope requires that the wave form be repetitive and is therefore not suited for finding extremely short-duration, nonrepetitive events (glitches).

6.1.1.3 Ranges. Oscilloscopes are equipped with several user-selectable time-base values and voltage ranges. The time bases range from several seconds down to a few nanoseconds. Most oscilloscopes are equipped with a 10× scale expansion of the time base, which is useful when trying to observe very fast events. The voltage ranges are front-panel selectable from 1 or 2 mV per division to 5 or 10 V per division. The voltage ranges may be extended upward through the use of a 10× or 100× attenuator probe.

6.1.1.4 Triggering. Triggering is the ability to synchronize the oscilloscope trace with some feature or characteristic of the signal to be observed. This allows the initiation of the trace to be "held off" until some

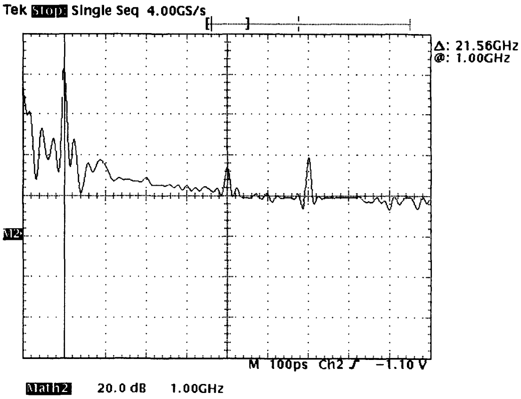

FIG. 4. Frequency-domain display of 1-GHz clock signal as measured on Tektronix 784 digital oscilloscope.

criterion is met. The criterion may be based on the magnitude of the voltage, the polarity of the voltage, the relative relationship between two voltages, or other events of interest. In the case of triggering the beam's movement on the basis of voltage level and polarity, the triggering control is set to either positive or negative depending upon the direction of interest, and the triggering level is adjusted accordingly. When the signal of interest moves in polarity in accordance with the criterion and reaches the preset trigger level, the beam moves across the screen and traces out the variations in the signal. In multichannel scopes, one input channel may be triggered on the basis of criteria established for one or more of the other channels. This triggering may also be delayed so that a trace does not begin until a specified time after the triggering criteria have been met.

In digital oscilloscopes, the triggering is performed quite differently than in analog oscilloscopes. In a digital oscilloscope the digitized signal is stored in a circular buffer. When the trigger condition is met, the stored samples are transferred to the display memory. The advantage of this method is that it is possible to look at the wave-form prior to the time the trigger occurred. This allows the analysis of a complex condition to include what has happened prior to the triggering condition being met.

6.2 Spectrum Analyzers

Spectrum analyzers are specifically designed to make possible the visualization and analysis of complex signals. This is accomplished by transforming the time-domain signal into the frequency domain. These instruments are able to accept a signal containing many frequency components and, through the application of Fourier analysis, to break the signal into its component frequencies. It displays the individual frequencies, the harmonics of those frequencies, and the relative magnitudes of each.

Such instruments are invaluable in the analysis of signals such as those obtained from mechanical equipment, biological and medical studies, radio astronomy, and any other area where it is necessary to identify the specific frequency components in a complex signal. Once a signal can be analyzed to determine its frequency content, appropriate filters and/or amplifiers can be acquired or designed to eliminate frequencies that lie outside of the area of interest or to amplify frequencies or bands of frequencies for further examination.

6.3 Network Analyzers

Network analyzers provide a convenient means for determining the transmission and reflection characteristics of electrical networks. These networks may consist of discrete components as in an electronic circuit or in distributed impedances such as cables. They may also be passive or active networks. A block diagram of a typical network analyzer arrangement is provided in Fig. 5.

Network analyzers operate by injecting a known signal into the network to be analyzed and comparing the network output signal with a known reference signal. The reference signal is obtained by passing the source signal through a power splitter, sending one half (by power level) to the network to be analyzed and the other half to the reference input of the analyzer. In this manner, the reference and test signals are known to be of the same frequency, phase, and magnitude. The signal that emerges from the network can then be compared to the reference signal to determine differences in magnitude and phase.

The source signal is swept through a range of frequencies in order to evaluate the network response or performance over a range of frequencies. The fact that the reference signal is derived from the same source minimizes the effect of any amplitude variations in the source. The network analyzer

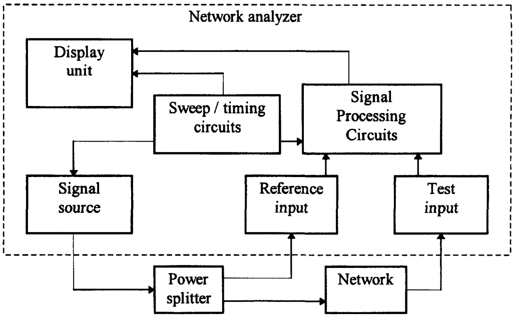

FIG. 5. Block diagram of network analyzer configuration.

may also be used to assess the degree of impedance matching in networks by measuring the reflectance.

On-screen markers are provided for ease of use and are controlled by a single front-panel knob, which allows the user to isolate points of interest for more detailed observation and analysis.

Network analyzers, like most of the current instruments, make extensive use of microprocessor and software technologies. Essentially all interaction with the system is through a CRT screen and software-programmed function keys. The extensive use of color CRT display technology allows for a better understanding and more rapid interpretation of the data being presented. The configuration settings may be saved on disk within the measurement system or on diskette as a record of the test setup; user programs and analysis procedures may be saved within the system as well as transferred to diskette. Extensive libraries of mathematical analysis routines are provided to aid in generation and analysis of test scenarios.

The sweep mode may be set for single-sweep mode, in which measurements are terminated following the initial sweep; continuous-sweep mode, in which case the sweep is automatically reinitiated following the last measurement in the current sweep; or a triggered-sweep mode, which requires a trigger condition to be met before the next sweep takes place.

6.3.1 Multifunction Meters The analog meter was the primary piece of easily transportable test equipment while equipment such as oscilloscopes, analyzers, and similar, more complicated instruments were generally considered to be laboratory-based equipment. Advances in microcircuit complexity and packaging have provided the ability to instill even more capability into the portable multimeter.

6.3.1.1 Digital Multimeter/Oscilloscope. An excellent example of increased functionality in portable equipment is the combined handheld multimeter, which incorporates the functionality of the multimeter (dc voltage, ac voltage, ac/dc current, etc.) and many of the capabilities of an oscilloscope. Such instruments are available from the Fluke Company, Tektronix, and other makers of test equipment. This equipment uses a relatively high-resolution liquid-crystal display (LCD) as the oscilloscope and conventional meter. The wave forms are "drawn" on the LCD display along with scale values and markers. A cursor may be moved along the wave form and the corresponding voltage value displayed on the screen in engineering units. Essentially all of the functions that are available on conventional CRT-based scopes and multimeters are being provided on handheld, digital-based configurations.

6.3.2 Frequency Measurement and Counters Frequency meters provide the ability to measure directly the frequency and period of an electrical signal. While the frequency of a signal may be determined by viewing on an oscilloscope and measuring the period of the wave form, it is generally not practical to do so in many applications. Since frequency measurement is based on the determination of the frequency with which a signal reaches a threshold level, similar circuits may also be used as counters. In the case of frequency measurement, the signal being measured must be periodic for the measurement to have any meaning. Frequency meters are available that can measure frequencies from 0.01 Hz to several gigahertz. Since counters only measure how many times a given signal meets a specified criterion (i.e., voltage level), the signal does not have to be periodic. It must, however, change sufficiently from the criterion to allow the circuit to reset and prepare for the next event. If the signal does not vary sufficiently from the triggering level, then, as far as the counter is concerned, there is no "new" event and therefore nothing to count. In both the frequency and counting modes, the detection threshold must be adjusted by the user threshold.

7. SIGNAL/COMMUNICATIONS LINK TESTERS

The measurement or verification of signal transmission parameters (refer to Fig. 1) may involve one or more types of measurement equipment. The signal being transmitted may be a simple dc voltage level (0–5 V), a current level (4–20 mA), an RF signal, a light signal (fiber optic), or a serial/parallel digital signal. The signal may be transmitted over a few feet or over several miles. The type of signal will determine the type of electrical test equipment used. In the case of a simple dc voltage level, a simple continuity test and voltage-level measurement using a portable multimeter will probably suffice; a current-level signal may be measured in a similar manner (it may be necessary to insert a small resistance in the circuit to convert the signal to a voltage since the series resistance of some multimeters may exceed the compliance voltage of the constant current signal source). The measurement of rf signals may require the use of a network analyzer or spectrum analyzer. Fiber-optic–based test equipment is available to support the troubleshooting and assessment of fiber-optic–based communication links. These include fiber-optic time-domain reflectometers to locate discontinuities in the transmission path. Digital communication "break out boxes" are available that allow a set of indicators and jumpers to be inserted in the communications path for observing transmission activity. Equipment is also available that allows the data transmission to be recorded for further analysis to aid in problem diagnosis. Traditional time-domain reflectometry test equipment is extremely useful in locating discontinuities in long (two to three miles) signal transmission cables. This is particularly useful if the signal path is buried or not directly visible or accessible.

8. PROBES

Probes are used to make actual contact with the electrical circuit or, in the case of noncontact measurements, to intercept signals emanating from conductors within the circuit for the purpose of making test measurements. There are several choices of probes, particularly for use with oscilloscopes. A probe may consist of nothing more than an insulated conductor such as a piece of wire, or may include active circuitry or clamp-on sensors used for making current measurements, or sophisticated, active probes used to make high-frequency or low-voltage measurements. An overview of the various types of probes commonly available is shown in Fig. 6.

8.1 Voltage Probes

Voltage probes are the most common type of probe. They can be relatively simple, as in the case of the passive probe, to more complex, special-purpose probes used for high-impedance, high-voltage, or differential-voltage measurements.

8.1.1 Passive Voltage Probes Passive probes do not provide any amplification of the measured signal and are the simplest and most common type of probe.

8.1.1.1 Low Impedance. Passive voltage probes can be as simple as an insulated conductor but more commonly employ some

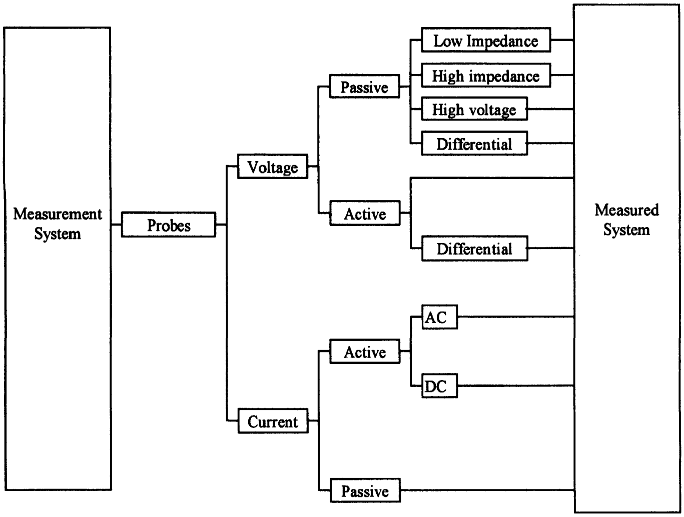

FIG. 6. Common probe types.

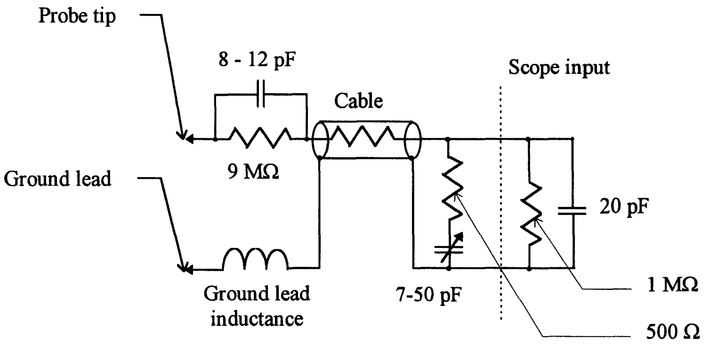

FIG. 7. Typical high-impedance 10× passive probe.

form of resistance configuration and are referred to as attenuating passive probes. These probes are designed to provide a convenient and inexpensive method of acquiring signals from most common circuit configuration and at voltages typically ranging up to 400 V. These probes present a 50-Ω impedance to the circuit under test. The common 10× passive voltage probe presents a higher impedance to the circuit and is useful up to frequencies of approximately 5 MHz. The main disadvantage of this type of probe is its relatively high input capacitance, which results in a decreasing input impedance with increasing frequency.

8.1.1.2 High-Impedance Passive Probes. High-impedance passive probes are similar in physical design to low-impedance probes. The difference is in the level of impedance presented to the circuit under test. The high-impedance probes are available in 1× and 10× attenuation and have a lower capacitance and therefore a higher impedance. This makes them suitable for higher-frequency applications, typically up to 500 MHz. A diagram of a typical 10× probe is provided in Fig. 7.

8.1.1.3 High-Voltage Probes. These probes are typically designed for use in measuring voltages in the range of 2.5–20 kV and frequency bandwidths to 250 MHz. High-voltage probes are available with 1×, 10×, 100×, and 1000× attenuation factors. This type of probe is generally used in power-conversion applications.

8.1.1.4 Differential Passive Voltage Probes. In some cases it is desired to know the value of a voltage that is referenced to some point other than circuit ground. Such measurements are referred to as differential-voltage measurements. An example is shown in Fig. 8. A measurement of this type is useful for determining voltage drops within a circuit, particularly in troubleshooting applications or design verification. Neither terminal of the instrument can be grounded (at or within the instrument) or it will effectively short R_2, resulting in a faulty measurement and possible damage to the circuit and/or instrument. This type of measurement can be made routinely using a handheld, battery-powered instrument. It is important, however, that the isolation voltage rating of the instrument not be exceeded. To measure accurately the voltage

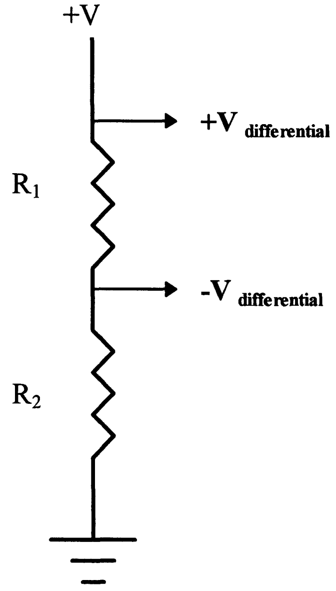

FIG. 8. Example of differential voltage measurement.

level difference between two points, the system used for the measurement must reject signals that are common to both test points and measure only the voltage difference. The degree to which the system rejects these common mode signals is called the Common-Mode Rejection Ratio (CMRR).

Such measurements can usually be made using battery-powered equipment since the electrical test equipment is effectively isolated from earth and circuit ground. Such measurements may also be made by using both channels of a dual-channel oscilloscope or with an active differential oscilloscope probe. On some oscilloscopes, it is necessary to invert one of the channels and subtract the measurement for the channels to obtain the differential. The need to invert and add the two channels may not be necessary on newer, high-end oscilloscopes that incorporate math capabilities. In this case one need only indicate that channel B is to be subtracted from channel A and the oscilloscope performs the required operations, thus yielding the differential signal.

Such a measurement is very useful in circuits that use differential drivers, such as in digital communications circuits. Differential driver circuits are used in such applications to avoid the problem of inconsistent ground levels between two widely spaced facilities. Since each side of the circuit is referenced only to the other side and not to a specific ground level, there is no uncertainty resulting from differences in ground potential between the two ends of the circuit. Such a configuration is shown in Fig. 9.

Another method of avoiding ground loops and also providing a very high degree of circuit isolation is optical isolators and fiber-optic links. In these applications, the electrical signal is converted to light, transmitted, then converted back into an electrical signal. Because glass fiber is used to carry the signal, there is no direct electrical connection between the circuits and therefore no possibility for grounding problems. Optical isolators are individual circuits that are commonly used within circuits to provide local isolation between sections of a circuit.

8.1.1.5 Active Voltage Probes. These probes contain a field-effect transistor (FET) input circuit, which presents a very high input impedance to the circuit being measured. These probes are generally available in 1×, 10×, and 100× attenuation configurations with input capacitances on the order of 0.4 to 3 pF and input resistance from 1 to 10 MΩ. Input voltage ranges for these probes are generally limited to a maximum of ±200 V (dc + peak ac). They have bandwidths to several gigahertz depending on the particular model and manufacturer.

Specific power supplies are available to allow this type probe to be used with equipment that does not directly support such probes. This type of probe is used in the design of high-speed analog and digital circuitry.

8.1.1.6 Differential Active Voltage Probes. These probes are used in the same manner as passive differential probes but are equipped with active FET amplifiers in each probe to reduce circuit loading. In addition, these probes are used with a dedicated differential amplifier to provide a single-ended

output. These probe/amplifier systems provide high sensitivity and high CMRR (typically 100 dB).

8.2 Current Probes

The measurement of current flowing within a conductor may involve insertion of the measurement device directly in series with the circuit or encircling the conductor with an appropriate probe that intercepts the magnetic field induced by the flowing current. The direct insertion of the measurement device into the circuit generally does not involve the use of a probe. The encircling of the conductor does require the use of some form of current probe. Current probes may be constructed in two styles; split core and solid core. In order for the current probe to couple with the maximum magnetic flux, it must encircle the conductor in which the current is to be measured.

The probes described in this section are generally available in current ranges from 200 to 300 ma to several hundred amperes dc, 1 to 2 amperes to 2 kA ac. They are useful at bandwidths of dc up to 1 GHz depending on the particular manufacturer and configuration.

8.2.1 Passive Current Probes This type of probe is used for the measurement of ac currents. The ac current causes a buildup and collapse of the magnetic-flux field surrounding a conductor. The passive probe utilizes a transformer coupled to this flux field to produce a voltage. This voltage is then used as a measure of the current flowing in the conductor. These probes are termed passive since they do not require any external power to operate. In a split-core configuration passive probe, the probe can be opened and clamped around the conductor. In a solid-core configuration, the conductor must be passed through the core, thereby requiring that the circuit be broken for the insertion of the probe element. When a solid-core configuration is used, it may be included as a permanent or semipermanent part of the circuit with the measurement instrument connected to the probe when a measurement is to be made.

A disadvantage of the transformer configuration is that the transformer core may become saturated as a result of a large current flowing in the conductor, thereby rendering the probe highly inaccurate. A key factor associated with current probes is the amp*second product. The saturation of the core material is a function of both the average amplitude of the current and the time for which it is applied. The product of these two quantities is called the amp*second product. Generally speaking, each current probe manufacturer will have a specified limit for the amp*second product. As along as the probe is operated in conditions that do not exceed this specification, the probe output will remain linear and provide an accurate measurement.

An approach taken to overcome this problem is the application of a reverse current, which is equal in magnitude to the current being sensed, through the probe. This has the net effect of minimizing the level of current "seen" by the probe and therefore avoiding core saturation.

8.2.2 Active dc Current Probes The varying flux field surrounding a conductor carrying an ac current provides a ready means of measuring the current. However, in a circuit in which a dc current is flowing, there is a steady-state magnetic flux surrounding the conductor. In this case, a Hall-effect device is used to sense the magnetic flux and convert it to a voltage signal. dc current probes are termed active probes in that they require external power to operate the Hall-effect device.

8.2.3 Active ac Current Probes Active ac current probes incorporate both the transformer principle used in passive ac probes and the Hall-effect principle used in dc current probes. This configuration is useful in applications that involve an ac current component in conjunction with a dc current component. This type of probe configuration allows such currents to be measured simultaneously with a single probe. This type of probe is also needed to measure signals such as a square wave where the signal may switch on and off and never go below zero. In this case, not only is there an ac component, but there is also a significant dc current component.

8.2.3.1 Clamp-On. While voltage measurements are made across terminals within a circuit, conventional current measurements require the breaking of the electrical circuit and the insertion of a shunt. Clamp-on probes eliminate the need to break the electrical circuit and are now the most generally used instrument for measuring both ac and dc current. These devices include both Hall-effect sensors and inductive-pickup types. Clamp-on ammeters are very common and are used for ac current measurements ranging from a few amperes to several hundred amperes. These are fully self-contained devices, which have a convenient hand grip that opens the jaws of the meter and allow its placement around the conductor. Hall-effect clamp-on probes are used in probes for oscilloscopes and allow the precise measurement of low-level, fast–rise-time currents.

8.2.3.2 Special-Purpose. Special-purpose probes include low-capacitance oscilloscope probes and active probes. Active probes include some form of amplification or impedance-matching circuitry, which is powered from the test equipment or a separate power supply. This type of probe allows for the measurement of high-frequency signals, typically to 1.5 GHz. These probes have an input capacitance of <1 pF and an input resistance of 1 MΩ, which allows for the measurement of extremely fast, low-level signals that would otherwise be altered by the relatively low impedance of ordinary probes and test equipment. These probes must be adjusted to specific circuit conditions in order to make correct and precise measurements.

8.2.3.3 Calibration/Compensation. A simple probe used to make voltage measurements usually does not require calibration since it is generally nothing more than a conductive shaft. However, in situations where the probe contains internal resistive, capacitive, and/or inductive components, it is important to check the probe periodically against manufacturer's specifications, particularly in rugged or abusive environments and where critical measurements are to be made.

The more sophisticated probes such as Hall-effect, inductive, and high-frequency, active probes require more frequent and comprehensive calibration since there are more components to drift out of calibration or be affected by adverse conditions. It is customary to calibrate some types of probes for use with a specific piece of equipment (probes and the associated equipment may not be readily interchangeable).

Probes used with oscilloscopes are generally equipped with an adjustment that allows for compensation for the probe's impedance effects. This may be accomplished by adjusting a small variable capacitor located within the probe body. On the more modern oscilloscopes, automated compensation and calibration features are provided. The user need only connect the probe to the output terminals of the calibrated signal source provided on the oscilloscope front panel and select *gain compensation.* The oscilloscope proceeds to perform the necessary gain compensation and verification of probe performance.

9. FACTORS AFFECTING ELECTRICAL MEASUREMENTS

In order for an electrical measurement to be of practical value, it must be repeatable, accurate, and stable. Several factors can have an adverse effect on making electrical measurements that meet these criteria. The most common include electrical and/or magnetic noise, poor or improper grounding of either the test equipment, the equipment to be measured, or both, and loading or otherwise influencing the circuit to be measured by the very application of the electrical test equipment. Each of these areas is addressed in more detail in the following sections.

9.1 Noise

For the purposes of this discussion, noise is defined as any signal other than the desired signal to be measured. There are several sources of noise that may be encountered in the course of making electrical measurements. Noise may be generated within the circuit being measured or may be generated external to the circuit and coupled into the circuit. The specific units of measurement of noise are dBm/Hz, dBμV/Hz$^{1/2}$, and μV/Hz$^{1/2}$. Noise is of serious concern in making accurate and repeatable electrical measurements. If a sensitive, low-level measurement is to be made, but the desired signal is "buried" in a background of noise, steps must be taken either to better identify the desired signal in the presence of the noise or minimize the noise (band-pass, band-limiting filters). In many cases, excessive noise may be attributable to poor or nonexistent grounding. An example might be in making measurements with an oscilloscope probe without properly grounding the probe or scope.

9.1.1 Externally Generated Noise In many situations the signals generated by the commercial power grid can be coupled into the test equipment and/or the circuit to be measured. The noise manifests itself at a frequency that corresponds to the power-line frequency, typically either 60 or 50 Hz (other frequencies may be encountered depending upon the ac power source; e.g., 400 Hz in military applications), and also at harmonics of the line frequency. Mechanisms for noise transmission and coupling include inductive pickup, capacitive coupling, electrostatic pickup, and ground loops. Inductive pickup occurs since any conductor carrying a varying current is capable of inducing a similar current in any conductors that lie in close proximity and are oriented so as to maximize coupling. A common mechanism for such coupling is the alternating fields generated around power wires installed in the walls, floors, and ceilings of buildings. Unless proper steps are taken to shunt or shield sensitive circuits and test equipment from such fields, low-level ac signals will be induced within the circuits. Electrostatic pickup occurs as a result of a circuit or test equipment being placed within a space that contains a high electrostatic gradient. Electrostatic pickup is most noticeably encountered when using high–input-impedance test equipment that is not properly connected to the circuit to be measured or is not properly grounded. Other sources of externally generated noise include fluorescent lighting, induction motors, and electrical contacts in motor and power equipment.

9.1.2 Internally Generated Noise Electrical circuits are also capable of generating noise internally. Noise internal to a circuit is generated by resistors, semiconductors, vacuum tubes, and virtually every component of the circuit. Although the magnitude of the noise may vary considerably depending upon the mode of generation, it is still necessary to have at least an awareness and understanding of noise sources internal to the circuit being measured. All conductors and semiconductors in a circuit generate *thermal noise* (also known as *Johnson* or *Nyquist* noise). This noise is produced as the result of thermal agitation of free electrons. The noise voltage generated across a resistor can be expressed as

$$\overline{e_n^2(t)} = 2kTRd\omega/\pi,$$

where $k = 1.38 \times 10^{-23}$ JK (Boltzmann's constant), T = temperature in Kelvins, R = resistor value in ohms, and $d\omega/2\pi$ = frequency band (centered at angular frequency ω). Thus, the resistor appears as a voltage source within the circuit with a mean squared open-circuit voltage of $\overline{e_n^2(t)}$.

9.1.3 White and Colored Noise The term white noise is derived from the concept of white light. White light contains a multitude of frequencies of light, red, violet, blue, green, etc. The term *white* noise as applied to electrical noise has the same connotation, the difference being that electrical noise does have a restricted bandwidth. The specific technical definition of white noise is noise such that the power in a frequency interval of fixed size is the same regardless of the interval chosen. Any other noise is *colored;* e.g., "pink" noise has higher power in the lower frequencies. Probably the most predominant noise is that found when trying to tune an AM short-wave radio, the ever present background white noise signal. Similar noise signals are generated when appliances that employ brush-type induction motors are operated. The noise generated by the arcing brushes generates a reasonably broad-band noise signal. Other sources of noise include fluorescent lamps, solid-state motor speed-control circuits, and automotive ignition systems.

9.1.4 Signal-to-Noise Ratio The magnitude of the desired signal as compared to the background noise level is referred to as the signal-to-noise ratio (SNR). It is desirable to maximize this ratio in order to obtain the clearest signal. This may be accomplished by employing properly designed filter circuits or by controlling the noise contribution of circuits such as amplifiers. An amplifier used to boost the desired signal also contributes noise since it too contains elements that are noise sources. The signal-to-noise ratio is measured in decibels, as this provides a wider dynamic range of measurement.

9.2 Grounding

There are basically two types of grounding: direct connection to the earth, and connection of power circuits to the circuit ground (which may in turn be connected to earth ground or not). Poor grounding can contribute significantly to the pickup and generation of noise. Such faults can arise from many sources, all associated with faulty grounding. In addition to erroneous measurements and confusing results, poor grounding may also result in personal injury. If a circuit is designed to be connected to earth ground, it must be properly connected to earth (safety) ground to eliminate the possibility of noise generation or electrocution. If a circuit is designed to "float" but is inadvertently connected to ground through dampness, contamination, or improperly connected equipment, erroneous measurements may arise. Many pieces of electrical test equipment are designed with internal shields around sensitive circuits within the instrument. These shields are grounded both to the internal circuit ground and to earth ground through the three-prong plug. This provides a direct path to ground for any spurious signals that might otherwise be picked up by such circuitry. A common problem in making electrical measurements is referred to as the "ground loop." Ground loops may originate from several situations but are generally attributed to leakage paths between circuits. Ground loops may be avoided by carefully reviewing grounding connections, and providing circuit isolation (e.g., optical isolators or transformer coupling).

Grounding problems can also arise as the result of routing the "return" circuits for power circuits back through a common, improperly sized ground conductor. The ground (negative) conductor has resistance and therefore results in a voltage drop across it. If the ground conductor is not of sufficient size, a substantial voltage drop across the ground conductor may result. This causes the circuit to rise to some potential level above ground potential. This may not pose a significant problem unless the circuit is connected to other circuits that are referenced to ground through alternate paths. An example of how such a situation may arise is illustrated in Fig. 10.

9.3 Loading

The direct attachment of electrical test equipment to the circuit to be measured may influence the measurement as a result of *loading*. Since the voltmeter (or similar types of equipment) is an electrical device, it possess the same characteristics as the circuit being measured. The degree to which the measured circuit is influenced depends upon how close the impedance of the device being used is to the impedance of the circuit being measured. An example is shown in Fig. 11. The meter being used to make the measurement has an input impedance of 1 MΩ. The portion of the circuit being measured has an equivalent impedance of 10 MΩ. The introduction of the test equipment in order to make the measurement alters the circuit being measured by effectively introducing a "new" circuit configuration. Such conditions not only can produce erroneous measurements, but in the case where a circuit may be oscillating, an undesired condition, the introduction of test equipment may alter the circuit to the point where it no longer oscillates. Under such circumstances, what is ob-

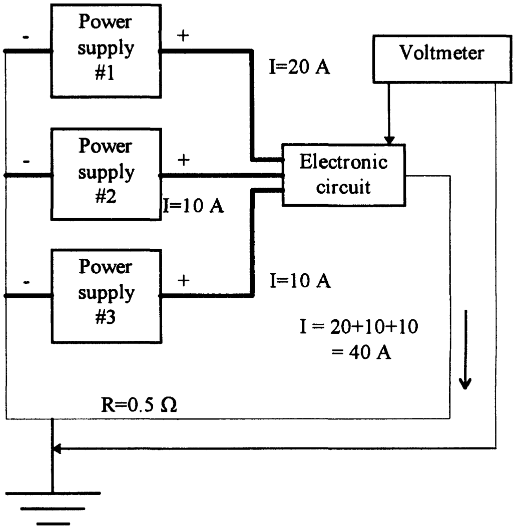

FIG. 10. Improper grounding through undersized conductor. Voltage drop across ground return is 0.5 Ω times 40 A or 20 V, therefore the circuit being measured is 20 V "above" ground.

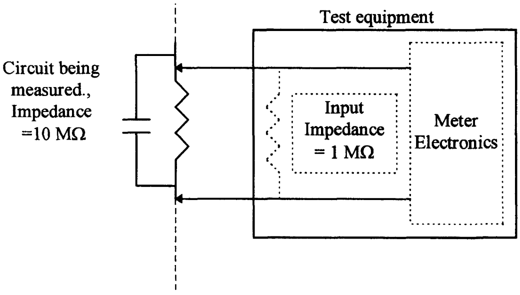

FIG. 11. Example of circuit loading by test equipment.

served when the test equipment is not connected may not agree at all with what is seen after the equipment is attached. Care should always be taken to observe the effects the test equipment may have on the system being measured.

9.4 Aliasing

Aliasing occurs when a measured signal has frequency components at or higher than the sampling rate of the digitizing equipment. Such high-frequency components can result from the inherent noise of the measurement system or from the system being measured. Sources of such noise include 50- or 60-Hz pickup from the power lines, broadcast stations, mechanical vibrations, and other sources. High-frequency components may also result from sharp transitions in the measured signal. If the signal being measured is not properly band-limited to prevent these higher-frequency components from being sampled, then they may "fold back" into the signal of interest and result in measurement error. The sampling frequency is less than twice the highest frequency of the signal being sampled; therefore, a lower-frequency component is introduced resulting in an erroneous measurement. This problem occurs more frequently in data-acquisition systems that do not incorporate proper anti-aliasing filtering at the input. Once the signal is sampled and the aliased signal is present in the data, it cannot be removed. It is therefore important to band limit the input to the measurement system or make certain that the sampling system is capable of sampling at least twice the frequency of the signal to be sampled (Nyquist criteria).

10. ELECTRICAL TESTING EQUIPMENT PHYSICAL CONFIGURATIONS

Electrical test equipment comes in several configurations owing to the rapid development of microcomputer, miniaturization, software, materials, battery, power supply, and integrated circuit technologies. Test equipment functionality once available only in bulky equipment that had to be powered from line voltage has evolved from bench-top and rack-mounted configurations to more portable and even handheld configurations. Sophisticated measurement capabilities including full-function oscilloscopes are now available in handheld, battery-powered configurations.

10.1 Handheld

Handheld test equipment refers to that category of equipment that can be transported and used while holding the instrument in one hand and probing the circuit to be measured with the other hand. Until the past few years, handheld electrical test equipment was generally limited to volt-ohmmeters (VOMs), or multimeters such as the familiar Simpson®/volt-ohmmeter. Advances in microcircuit, microcontroller, and microcomputer technologies have allowed more sophisticated functions to be incorporated into handheld test equipment. Examples of these include digital oscilloscopes, signal acquisition and analysis equipment (digital signal processing and spectral analysis), and handheld successors to the traditional multimeter that include meters with combined analog and digital displays. These meters provide the ability to measure very accurately ac and dc voltage, ac and dc current, true rms voltage, resistance, frequency, capacitance, and diode test, as well as other functions depending on the particular model. Handheld, LCD-based oscilloscopes are now widely available and can prove very useful in making field as well as bench-top measurements.

Although they may be line powered, this class of equipment is almost always battery powered in order to provide maximum utility and application in field environments. When using this type of equipment to make measurements where the entire instrument will be above ground potential (i.e., floating), it is *extremely* important to follow the manufacturer's warnings regarding maximum isolation voltage for the instrument. This is the maximum voltage to which the instrument's overall insulation is rated. If this voltage level is exceeded, it is possible for the electric current to pass from the test points, through the instrument, and into the body of the person holding the instrument. While such precautions also apply to portable and rack-mounted equipment, these types of equipment are usually connected to earth or safety ground and therefore provide an alternative path in the event of dielectric breakdown.

10.2 Portable

Portable electrical test equipment generally refers to larger–form-factor test equipment that can be transported by a single individual and is intended to be used in remote or field locations or merely for ease of transfer from bench to bench. Such equipment includes oscilloscopes, spectrum analyzers, power supplies, function generators, and similar equipment.

10.3 Rack-Mounted

Traditionally the term rack-mounted referred to test equipment that was semipermanently mounted into a metal rack. The opening of the rack was based on a standard 19-in. (48.3-cm) opening (to mounting centers). The instruments, while varying in height and depth, must conform to this standard horizonal rack-mounting requirement. Virtually every type of electrical test equipment is currently available in this form factor.

Newer test-equipment configurations are now also based on vertical rack arrangements referred to as card cages. The most common of these are the NIM, CAMAC, VME, VXI, and MMS configurations. The NIM and CAMAC formats have been used for many years, particularly in high-speed nuclear instrumentation. The VME, while considered to be more of a computer-oriented instrument format (digital input/output, analog-to-digital converter, and digital-to-analog output), is the predecessor to the more general class of modular instruments known as VXI. MMS or Modular Microwave System modules also include a wide assortment of instruments but do not seem to be as popular as the VXI because of their higher cost. Unlike the 19-in. rack-mounted configuration, which imposed only the physical width requirement, these rack-mount standards dictate module heights, widths, and depths, maximum power consumption, maximum cooling requirements, and the relative degree to which instruments may interfere or interact with their "neighbors." The standards also dictate how data and information are to be communicated between modules and between a module and the "crate controller."

10.4 Instrument-on-a-Card

The advent of instruments adapted to direct insertion into the personal-computer backplane and even into laptop and notebook computers has led to complete instruments being placed on a single card using the computer itself as the display and control interface to the instrument. The instrument-to-computer interface may be in the form of PCI or EISA for rack-mounted or desktop computer configurations, or PCMCIA for laptop and notebook computer configurations. While not yet providing the level of sophistication of dedicated, application-specific electrical test equipment, such implementations can prove useful in some applications. It is important to note that the performance of this type of instrument can be heavily dependent upon the type and performance of the computer to which it is attached and is not intended to replace high-performance specialized test equipment. Examples of such instrument-on-a-card configurations include spectrum analyzers, voltmeters, and oscilloscopes.

11. DISPLAY CONFIGURATIONS

The presentation of information obtained from electrical test equipment is important in interpreting the test results. The advent of new display technology has made it much easier to interpret data and even to present data in graphic form in handheld instruments.

11.1 Analog

The traditional method of displaying test measurement data has been through the use of a simple analog meter. The advantages of the analog meter include low cost, simplicity, and ease of reading. Although well suited for simple voltage and current display, the conventional analog meter display has been limited in application to single-parameter display and for "relative indication." This latter function, relative indication, refers to the ability to just glance at an analog display and quickly get an assessment of the magnitude of the parameter without actually having to "think" about the precise measurement. This had led to the implementation of bar-graph and other analog-type indicators using digital-display technology. Some instruments implement the traditional analog "meter" display using digital "icons," which mimic a traditional analog meter to provide the same "quick look" capability.

11.2 Digital

The advent of the light-emitting diode (LED) display and liquid-crystal display (LCD) have made it very easy to display data in digital form. In a digital-display–based instrument the voltage measurement is made through the use of an analog-to-digital conversion circuit. The measurement is quantified and sent to a digital-display circuit, which conditions the data for the LED or LCD display unit. The LED display offers the advantage of ease of viewing in low–light-level conditions at the expense of requiring significant power to energize the display elements. The LED display may also be difficult to read in high ambient light such as direct sunlight. The LCD display offers the advantage of extremely low power consumption. The primary disadvantage of the LCD is the difficulty in viewing the display in areas of low light level. Provisions have been made in some instruments to provide a back-lighting capability in which a small lamp may be energized to illuminate the display from behind, thereby making it viewable. Of course this is counter to the reason for using an LCD display, i.e., low power consumption. In field applications where instruments may be exposed to extremes of temperature, consideration should be given to the tendency of the LCD display to blank out or become inoperative at very low (freezing) or very high temperatures (e.g., inside of vehicles).

11.3 Graphic

Often the most useful form of data presentation is in graphic form. This is particularly useful where trends are to be observed or high-speed events need to be observed. Until recently the most common form of graphic data display has been the oscilloscope. These instruments provide a graphic plot of voltage variations as a function of time. Many instruments now utilize CRT (and LCD) technology to provide graphic presentations of complex data. Common examples of these include spectrum analyzers and network analyzers, which display the results of FFT transforms directly on the screen. Increased use of microprocessor and LCD technology have resulted in even more powerful methods of graphic data presentation. A very useful application of this technology has been in the display of complex information in handheld instrumentation such as handheld, battery-powered oscilloscopes. The introduction of a wide variety of plug-in boards and modules for the personal computer combined with the processing power and color display capabilities of the personal computer have made the graphic display of information in real or near-real time a relatively simple task.

12. VIRTUAL INSTRUMENTATION

Traditionally an electrical measurement was made by manually interacting with the front panel of the instrument to select type of measurement, set the desired measurement range, initiate the measurement, and record the results. The advent of the *virtual instrument* concept makes it possible to interact with electrical test equipment without ever having to touch or view the actual equipment directly. Essentially the virtual instrument is a graphic representation of the controls and display found on an actual instrument. The measurement to be made using the instrument is accomplished through the use of software commands to various modules or, in some cases, actual instruments. An example would be the display of the controls and displays of a conventional multimeter on the CRT display of a personal computer. The user interacts with the virtual instrument through the use of the keyboard or *mouse,* selecting the desired measurement, etc. The computer, which is connected to an electronics module (which has no front-panel display or controls—e.g., VXI module) through a communications link, transmits the control information to the module, acquires the measurement, and displays it on the computer monitor. The advantages of such instrumentation is that it minimizes desk or rack space that would be required for conventional rack-mounted equipment, allows sharing of instruments among several users, supports more sophisticated data analysis, recording, and sharing, decreases weight, permits virtual interconnection of equipment, and provides ease of measurement automation.

13. INTERFACING

In many cases it is desirable to acquire measurements from electrical test equipment that is situated in a remote or not easily accessible location. Or it is not economically feasible to measure and record the data manually. Rather than manually record data obtained by an instrument, it is possible to have the instrument automatically polled to obtain the data from a remote location and transmit the information to a central location for processing. This section describes some of the mechanisms that provide for easy interfacing between electrical test equipment.

13.1 General-Purpose Instrument Bus (GPIB)

Many instruments provide the ability to be interconnected by means of standard interface mechanisms. One of the most popular for individual instruments is the IEEE-488 protocol, also referred to as the *general-purpose instrument bus or GPIB.* This standard employs a well-defined standard cable and connector configuration to support interconnection of instruments and computers. It also employs a well-defined communication language protocol. This language consists of a library of specific function calls, which may be used both to program and to interrogate an instrument. The commands are listed in the user's manual, with some being unique to a particular instrument.

Through the application of such an interconnecting link, it is possible to build networks of instruments and to acquire data automatically from many instruments. A key feature of the GPIB interface is that it is a multidrop link. This means that many instruments may be linked to a single cable link and that new instruments may be added by just connecting them to the existing link by means of an additional cable. This ability to interrogate, configure, and control specific instruments over a computer link is in itself a very powerful feature. It also plays a critical role in the application of virtual-instrument concepts (see Sec. 12).

13.2 Dedicated Instrument Bus

Dedicated instrument buses (e.g., VXI) are those that are based on a back-plane configuration designed for specific instrument physical configurations. These buses generally provide a means for instruments to communicate with a computer to support configuration, control, and interrogation. These buses may be used to provide a compact configuration, high-speed measurement, multipurpose functionality, or a combination of these. Provision is usually made through the use of bus expanders to daisy-chain back-plane enclosures, thus providing for expansion.

13.3 Serial Instrument Communication

Serial data communication links (e.g., RS-232, RS-422) provide a low-cost and relatively simple method of obtaining data from electrical test equipment and in some cases providing a means to remotely configure the equipment.

13.3.1 RS-232 A very common instrument link is the RS-232 or Serial Link. This link is used primarily between a single instrument and a computer or data-logging equipment. The term "serial" refers to the fact that the information to be transmitted (in digital form) is sent one bit (binary digit) at a time in a serial fashion. This standard originated primarily for terminal-to-computer and computer-to-computer communication. Its use has since been extended to device-to-device and device-to-computer communication. The major disadvantage of RS-232 links is the inability to link more than one device to a communications path; i.e., it does not provide multidrop capability. Each device must have its own dedicated link to the central device (computer or data logger).

13.3.2 RS-422 The RS-422 serial communication standard was developed to counter the lack of multidrop capability in the RS-232 standard. The RS-422 standard allows up to 16 devices to be "dropped" from a common communications "backbone." The standard provides the mechanism for individually addressing each instrument on the bus and receiving responses from the instruments.

14. CONCLUSION

A wide variety of electrical test equipment is available, each well suited to specific areas of electrical circuit measurement. The advent of and continued progress in microprocessor and microcontroller technology, integrated circuits, and software have provided ever smaller and more powerful electrical test equipment. Much of the analysis that had to be performed manually prior to the advances in instrumentation is now performed routinely within the instrument. The ability to link a variety of electrical test equipment into a "measurement system" configuration and to operate in a virtual-instrument environment is a very powerful consideration when large numbers of measurements must be made or changes in measurement configuration are frequent.

Almost all electrical test equipment may be used to obtain measurements across the areas of power sources, power conversion and conditioning, component measurement, and signal measurements. However, some types of equipment are better suited to specific measurement areas than others. The user should carefully consider the specific application and determine the best type of equipment to use. A review of the free (or low-cost) applications notes and test-equipment data available from electrical test-equipment manufacturers can prove to be very helpful when deciding how best to make a measurement or the type of equipment to use.

GLOSSARY

Active Components: Electrical circuit elements such as transistors and tubes. Active components are used in the generation, control, and amplification of electrical signals. As examples, active components serve as switching elements, signal amplifiers, and oscillators. (See also **Passive Components.**)

Active Probe: An instrumentation probe that contains active elements such as field-effect transistors and is designed to provide signal amplification or to minimize loading effects on the circuit being measured.

Common-Mode Rejection Ratio (CMRR): A figure of merit for a differential amplifier. It is defined as $CMRR = |A_d/A_c|$, where A_d is the voltage gain for the difference signal and A_c is the voltage gain for the common-mode signal. A perfect differential amplifier has a CMRR equal to infinity. The higher the CMRR for the difference measurement system, the closer it is to the ideal. As an example, with a system CMRR of 10 000:1, a common mode input of 5 V will result in an output of 0.5 mV. CMRR may also be expressed in dB: CMRR (dB) = 20 log CMRR; e.g., a CMRR of 10 000:1 would be a CMRR of 80 dB.

Effective or rms Value: The effective or rms value of a varying power is the measure of the amount of energy being transferred in an electric circuit. The true rms value is the rms value of a voltage independent of the wave form of the voltage.

Hall Effect: The effect whereby a steady current, flowing in a steady magnetic field, gives rise to an electromotive force that is at right angles to both the magnetic field and the current. The electromotive force is proportional to the product of the intensity of the current, the magnetic field, and the sine of the angle between the direction of these quantities.

Instantaneous Power: Instantaneous power for an alternating voltage and current is the product of the instantaneous voltage and instantaneous current at the same instant.

Passive Components: Electrical circuit elements such as resistors, capacitors, and inductors. Passive components, by themselves, do not alter the frequency or wave form of an applied signal. They may only introduce phase shift and/or alter the magnitude of an applied signal.

Passive Probe: An instrumentation probe that consists simply of a conductor or, in the case of attenuated probes, resistive and capacitive elements.

INTRODUCTION

This article focuses on determining the mechanical properties of materials as well as the mechanical response or structural integrity of components and systems (assembled parts). Success in testing depends on how tests are planned, what insights are desired, and how tests are conducted. Specific reasons for performing tests include the following:

- to complement and confirm analyses of the response of mechanical systems to applied forces;
- to determine mechanical properties of various materials as functions of temperature, strain rate, and other test conditions;
- to satisfy laws or regulations such as acceptance of a part or system for service in commercial or military applications;
- to determine acceptance of mechanical parts by simple pass/fail evaluation criteria (e.g., a pressure proof test on a gas cylinder);
- to determine mechanical behavior independent of time (e.g., static strength tests on test items and assemblies);
- to determine time-dependent dynamic responses of materials and assemblies (e.g., fatigue resistance of critical composite aircraft assemblies); and
- to serve as the only source of understanding as to how assembled parts actually respond.

The minimum requirements to perform mechanical testing are that

1. a physical item (e.g., specimen or structure) must be available for testing,
2. test equipment must be available for use and capable of imposing a measurable stimulus to the test item, and
3. the test equipment and/or test item must be equipped with transducers or other devices needed to measure the stimulus to and response of the test item.

Guidance for performing tests is available from many sources. Standards and procedures for tests on metals are described in the ASM Metals Handbook (1985). Standards and procedures for tests on wood and timber products are described in the USDA Wood Handbook (1987). The American Society for Testing and Materials publishes standards, procedures, and references for tests on nearly all materials in seven broad categories:

1. iron and steel (series A),
2. materials for electrical applications (series B),
3. natural and man-made non-carbon-based materials (series C),
4. typical carbon-based materials with long-chain molecules (series D with some exceptions such as soil and rock mechanics),
5. characteristics of materials (series E),
6. applications including but not limited to tires, gaskets, paper (series F), and
7. corrosion and wear (series G).

The fundamentals of structural testing are described by Reese and Kawahara (1993). This basic handbook provides the details required to perform successfully a wide variety of tests. Relationships among engineering mechanics, materials science, and structures (mechanical assemblies) are described by Blake (1985). Relationships in materials sciences were reported by Van Vlack (1974) and Davis *et al.* (1982).

Attachment of test items, assemblies, and measurement equipment to test equipment or systems is essential. Much of the art of testing originates in cleverness in design and fabrication of fixtures. Fixtures provide the boundary conditions for the test items, the means to apply forces, pressures, vibrations, or shock loadings. Fixtures are used for tension, compression, shear, and bending tests on metals, wood, plastics, and concrete and include cylindrical, rectangular, and tubular geometries. Fixtures are also important for attaching assemblies to vibration and shock test systems. The ASTM Standards (current editions), ASM Metals Handbook (1985), USDA Wood Handbook (1987), and Reese and Kawahara (1993) describe many fixtures. The importance of fixtures in testing specimens and assemblies cannot be overstated as they are the essential link between the test items and the testing systems and equipment.

Measurements are the principal products of tests. Measurements are made with sensors and transducers directly in contact with the test item or by noncontact techniques. (The use of contact or noncontact measurement techniques may be important in planning a test.) Among the test measurements reported in Doebelin (1975), Hannah and Reed (1992), Harris (1988), Tse and Morse (1989), and Wright (1994) are acceleration (linear, angular), displacement (linear, angular), force and torque, frequency, pressure, sound, strain, temperature, and velocity. In addition, nondestructive measurement techniques can also be applied to mechanical testing and contribute the following types of diagnostic methods as given in chapter 12 of Kobayashi (1987) and Reese and Kawahara (1993): acoustic emissions (sonic and ultrasonic), electromagnetic induction, magnetic, optical, penetrants, photometrics, radiography, and thermal. Tests performed on prototype aircraft often include both broad categories of experimental measurements as described in chapter 15 of Reese and Kawahara (1993). Measurements are made at local points of interest or over a portion or all of the test item or assembly.

Measurements of a given physical quantity can be made in a variety of ways. For example, test-induced displacements of an assembly or changes in length of a material test specimen can be made using

1. a dial indicator,
2. a transducer (linear potentiometer or a differential transformer),
3. ultrasonic transmission and reflection through the length or thickness of materials or parts, or
4. photometrics with camera or video coverage.

Strains can be measured using strain gages, optical moiré interferometry, and photoelasticity (specimens and coatings). The description of experimental mechanics methods and techniques were reported by Kobayashi (1987). Instrumentation and measurement systems are described by Beckwith and Buck (1973), Bendat and Piersol (1986), Herzfeld (1962), and Wright (1994).

Mechanical testing equipment supplies forces or excitations to test items. Included in the broad categories of forces and excitations are pressures, thermal gradients, shocks, vibrations, energy-producing modal or frequency responses, and other phenomena (e.g., rapid energy deposition) causing assemblies and/or materials to respond mechanically. Representative test environments that can be simulated are transportation, crash, blast, impact, hydraulic, rocket motor burn and separation, parachute loads, earthquakes, acoustic noise loads, centrifugal turbine loads, etc.

1. CONTROL METHODS AND CALIBRATION

Mechanical testing equipment is controlled in one of two basic ways: open loop or closed loop. Open-loop testing means that the equipment operator has control and provides feedback to the test equipment by modifying the rate of loading, thermal input, etc. Open-loop control is applicable to tests where time is not a critical parameter. Closed-loop testing means that a portion or all of the control of the test is given to the testing system itself. Closed-loop systems typically require interaction with and controls supplied by computers, function generators, or other electronic means. In actual practice, most test activities involve some open- and some closed-loop portions. For example, a test stimulus could be applied open loop and test results recorded closed loop.

Calibration of equipment is essential in providing quality test data traceable to national standards. This includes the mechanical test equipment, measuring transducers, and recording electronic instrumentation. The estimate of the uncertainties in measurements is an essential step in reporting test results.

2. TESTING SYSTEMS USED FOR DETERMINING MECHANICAL RESPONSES AND PROPERTIES OF MATERIALS

Test systems apply loads by mechanical and hydraulic techniques. Mechanical testing machines can apply forces through dead weights, screw drives, or other motor-driven (e.g., eccentrics and electrodynamic) coupling. Hydraulic machines can operate as tension or compression (e.g., manually operated pilot valve controlled) or tension and compression systems (e.g., servo valve controlled).

Testing systems can also be combined. For example, ovens can be installed around materials test specimens or test assemblies to obtain responses at elevated or low temperatures. Pressure systems and test items containing pressure can be subjected to multiaxial stress conditions.

The testing machines described in the four following sections (dead-weight, screw-driven, hydraulic, and servo-hydraulic) are self-contained systems as far as the forces are concerned. That is, forces are applied and equivalent reaction forces occur internal to the machines. The reaction forces and machine stability are supplied by the columns and the crossheads. When these machines have two reactive columns, they are vulnerable to the adverse effects caused by possible eccentric loads. If the forces transmitted to a test item result in a reaction force located a column diameter away from the plane or axis between the columns, the force capability of the testing system can be reduced by a factor of 4. If bending or side loads are generated during a test using any of the test systems in Secs. 2.1 to 2.4, then the use of a four-column or equivalent stiffened testing machine is recommended.

2.1 Dead-Weight Testing System

The dead-weight machine uses a series of weights attached to a lever to apply forces to test items. A typical use for dead-weight testing machines is in creep testing, in which the forces must be maintained accurately over long time periods. Force calibration is another example of the use of a dead-weight testing machine.

In Fig. 1, a lever-type dead-weight testing machine is shown. Stacked weights are shown on the elevator on the right side. The weights apply a tension force to a train and lever. The arm pivots about the fulcrum. The fulcrum is often movable so that different ratios of lengths (L_1 and L_2) can be obtained. The tensile force in the left load train resists the applied moment. The test item or specimen can be subjected to tension or compression forces depending on how it is attached

to this load train. Tension forces are applied by direct attachment to the load train. The applied tensile forces are resisted by a rod attached to the base plate and columns. Compression forces are applied through fixtures attached to the load train as shown in Fig. 1. A typical example of an associated fixture is a "compression cage" in which the test item is placed between two plates. The upper plate is attached to the lower tension rod, and the lower plate is attached to the upper rod. These plates have hole patterns that allow the connective hardware to pass freely through or to bypass the plates. In other variations to these machines the weights can also be applied directly to the test item.

2.2 Screw-Driven Testing Systems

An example of a screw-driven machine is shown in Fig. 2. The force is generated by moving the crosshead with lubricated, long, threaded columns or rods, which are turned by variable low-speed electric motors. Tension or compression forces are applied when

FIG. 2. Screw-driven testing system.

the crosshead moves respectively toward or away from the stationary top crosshead or the bottom platen. When tests are performed, the screws can be adjusted to provide crosshead motion at rates ranging from very slow to approximately 500 mm (20 in.) per minute. Tension or compression forces can be applied depending on the position of the test item, the direction of motion of the crosshead, and the attachment devices located in the main upper and lower support structures. For example, a test item would be in compression if it is placed in the bottom portion of the machine and the crosshead continues to move toward the base after making contact with the test item. Relatively recent advances have made it possible to apply both tension and compression forces (e.g., plus and minus torques) with very little inertial contributions using servo-controlled drive motors and linear direct-current amplifiers. The motors can be manually controlled with potentiometers, with function generators, and with interactive computer software. The motors and testing frame are protected with limit switches so that the movable crosshead does not become bound against either end and to prevent jamming the screw threads. The screws are often protected with movable covers to keep the lubricants from becoming contaminated, to keep the work area clean, to prevent entanglement of test items and hardware, and to reduce injuries to people.

2.3 Tension and Compression Hydraulic Testing Systems

These machines were originally called universal testing machines because they could supply either tension or compression forces but could not cycle between the two force modes. Since newer testing machines are capable of applying tension and compression forces, the term universal testing machine is now obsolete. These tension or compression hydraulic testing machines continue in service and have received many upgrades in terms of feedback, control, force, and displacement measurements. Figure 3 shows a typical two-column system. The hydraulic cylinder provides a force to the table. The table is attached to the upper crosshead by long columns and the applied forces can be transmitted to this upper crosshead. The movable crosshead is positioned for the test and, when stationary, provides the reaction point for the forces generated by the hydraulic cylinder. The tension space above indicates that the upper crosshead is moving away from the positioned movable crosshead during a test. The compression test area indicates that the table is moving toward the positioned movable crosshead. These machines typically have wedge grips or jaws built into or positioned in their crossheads. These grips or jaws are used to attach test items and have tension force capabilities equal to the maximum forces that can be generated by the machine.

These machines usually have 2.067-MPa (3000-psi) hydraulic cylinders located in the base of the machine. The hydraulic cylinder is machined to a tight tolerance within its case or capsule. A small amount of fluid is allowed to flow through the tolerance zone to lubricate the cylinder. The fluid thus used is returned to the reservoir, filtered, and recycled into the pump. The cylinder travels in one direction only and, since it is not sealed, can apply only compression forces on the top of the table, precluding cyclic tension and compression forces on a test item.

The control of these machines typically occurs through manual operation of pilot wheels controlling the flow of pressurized hydraulic oil into and out of the cylinder. One pilot wheel controls the loading, and one controls the unloading. Newer versions of these machines have been equipped with controls complementing manual operation so that load, stroke, and strain capabilities can be obtained.

2.4 Servo-Hydraulic Testing Systems

These testing systems are similar to the tension or compression testing machines in Sec. 2.3 in that the applied forces are transmitted hydraulically. Figure 4 shows an example of a servo-hydraulic testing system. The use of servo controls provides added test features when using this equipment. The sealed hydraulic cylinder provides actuator motion in two directions so that tension and compression forces can be applied. These systems are also equipped with built-in displacement gages (usually linear variable differential transformers, LVDTs) so that the displacement of the actuator can be defined

as well. Feedback controls are also available so that the load, stroke, or strain on a test item or specimen can be measured and used as part of the machine control. The crosshead can be moved manually, by using the hydraulic actuator and positioning blocks, or by hydraulic means. The hydraulic pump (not shown) may be built into the testing system or located at some other place for easier servicing, noise reduction, or space limitations.

These testing systems are equipped with load cells, displacement transducers, and feedback systems so that interactive control of load, stroke, and strain can be obtained. Strain control is obtained through extensometers or strain gages attached to test items. Some machines have the hydraulic actuator positioned in the crosshead, while others have the actuator in the base of the machine as shown in Fig. 4. These systems are capable of closed-loop operations because of the interactive controls, servo valves, and transducers. They can also be controlled by use of function generators or computer software interfaced with the hydraulics. A brief comparative summary of testing system capabilities (dead-weight, screw-driven, hydraulic, and servo-hydraulic) is given in Table 1. A servo-controlled actuator can also be attached directly to a structural frame or test bed as described in the following section.

2.5 Structural Frames and Test Beds

Structural test frames and beds accommodate large test items, test hardware having multiaxis loading requirements, large off-axis loading requirements, and other unique test requirements. A test frame or bed may

be small (e.g., milling-machine-table size) or large (e.g., aircraft-hangar size). Test items and hardware are attached to the bed or frame along with the loading systems. These beds or frames usually have a stiffened back or force reaction system. This force reaction system may be permanently attached or portable. Other beams, columns, and reaction systems are usually attached to the frame or bed. The large test frames or beds are serviced by overhead cranes, forklifts, and other related equipment for lifting and positioning test items, equipment, and loading systems.

Two examples of test frames and beds are shown in Fig. 5 as reported in Reese and Kawahara (1993). The first is a stiffened floor system (e.g., plates welded to beams) supported by four columns. The two rear columns also support a stiffened back. This back and floor system are the main force reaction systems. The only movable parts of this frame are the side rails and any portable beams, reaction systems, and loading equipment. The floor, beams, stiffened back, and columns have through or threaded holes on a uniform spacing to permit bolted attach-

ment of test items and hardware. This type of frame has the appearance of a giant erector set and is used many different ways to accommodate test items and equipment. It is not uncommon to have this type of frame modified in many ways to satisfy specific test purposes. Many of these frames have had extra plates, stiffeners, and beams welded to them, holes have been drilled for attachment of loading equipment and test items, and other modifications have been made for test purposes.

The second example consists of a stiffened floor system. This floor can have through holes, threaded inserts, slots, rails, or tracks embedded in it for attachment of test items, equipment, and loading systems. These floor systems are typically large and are used to test aircraft, bridge beams, and sections of buildings. Testing machines and systems have also been integrated into these floor systems. An example of an aircraft wing subjected to vertical forces is shown in Fig. 6 with the whiffle trees supplying the distributed pressures simulating aerodynamic forces.

2.6 Time-Dependent Tests and Equipment (Creep and Fatigue)

2.6.1 Creep Nearly all materials and structures made of them exhibit time-dependent behavior to some extent, depending upon the test temperature and environment, load magnitude, and load duration. Prestressed concrete beams and floor systems experience sagging under their own weight. The total strain at any point consists of recoverable and permanent parts. Each part

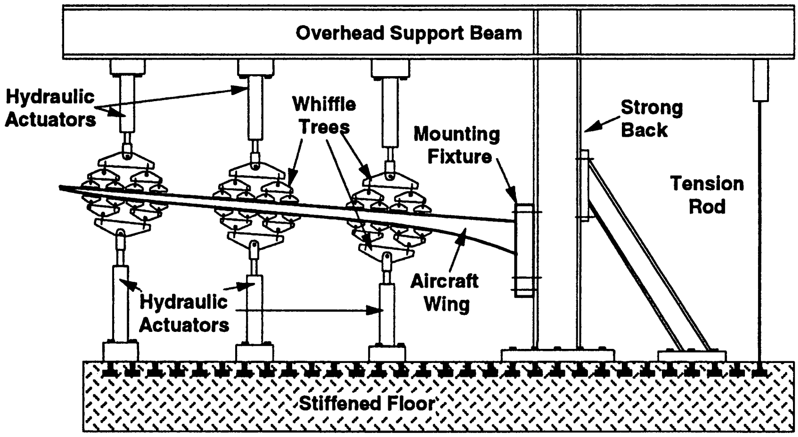

FIG. 6. Aircraft wing subjected to load tests on stiffened floor; vertical forces applied through whiffle trees.

may have time-independent and time-dependent components, again depending upon the test conditions.

For recoverable strain, the elastic component is relatively instantaneously recovered during unloading; its magnitude is usually proportional to the load. In stiffness testing, the load magnitude and duration are limited so that this elastic component dominates the total strain. For polymeric materials (and metals to a lesser extent) the elastic strain is often accompanied by a time-dependent anelastic strain component observed as an attempt by the structure to resume its original undeformed configuration for some time after unloading (i.e., residual strain at zero load that may decrease with time).

If the loading magnitude or duration (at a given test temperature) is sufficient, some of the total strain will not be recoverable even long after unloading; this is the permanent component of strain. The permanent strain can have a relatively time-independent component, the plastic strain, like that generated while yielding a steel tensile specimen at a constant velocity at room temperature. Or, it can be time dependent such as creep strain accumulating in the same specimen under contact stress at elevated temperature.

So, the total strain consists of time-independent and time-dependent recoverable and permanent parts. The proportions of these parts often change during a test. During a constant-stress tensile creep test on a metal, the elastic strain remains about constant while the creep strain increases with time. In a stress-relaxation test, a specimen is quickly strained a fixed amount; as the strain is held constant the load is observed to decrease. This is analogous to the preload decay in a nylon or soft lead washer after the bolt head is torqued. The decreasing preload means that the elastic strain is decreasing with time. Since the total strain is fixed, this elastic strain decrease is being balanced by an increase in anelastic and creep strain. For the nylon washer, it may be more anelastic than creep and vice versa for the lead washer.

The following identifies some failure modes that one should consider when creep behavior is anticipated. One should particularly be concerned when tests are requested at temperatures near or above one-half of the melting temperature (in kelvins) of any critical part under stress, especially for long loading durations, as reported by Bernasconi and Piatti (1979).

Excessive creep deformation leading to interference of parts is a failure mode. In turbine engines, rotor blades creep under radial centrifugal loads at elevated temperatures; the blade tips may engrave into the engine housing. As regards the grain-boundary sliding contribution to creep, one counter is to grow single-crystal blades; another is to form the blades superplastically (with very small grain size), then follow with a post heat treatment to dissolve most of the grain boundaries and recover the creep resistance inherent in the alloy.

Temperature cycling can cause excessive

deformation to accumulate as a result of incremental deformation. The source of this "ratcheting" can be time-independent plastic strains and/or time-dependent creep strains. For the latter, the phenomenon of "enhanced creep" may arise, wherein the creep strain accumulated during cycling exceeds that which would be calculated from continuous operation at the higher temperature boundary.

Stress relaxation in threaded connections can result in separation of parts and fatigue failure or reduction or loss of initial tension (preload). In aluminum electrical wiring, the loss of preload can result in a poor connection, high local electrical resistance, heating, and sometimes even fires.

Creep rupture is a catastrophic failure mode. For example, boiler vessels and high-pressure piping walls can reduce in thickness (a corrosive synergism may accelerate the process). Since the pressure is constant, the wall stress increases with thinning, thus accelerating further creep, thinning, and finally rupture. Empirical relations based on uniaxial tensile creep-rupture data can be used to help avoid creep rupture, although appropriate generalizations from uniaxial to multiaxial stress states is still a research topic as described in Reese and Kawahara (1993).

Creep crack growth under load can occur as the material near the crack tip progressively ruptures through void growth under high triaxial stress at elevated temperatures.

For slender members like columns and shell structures under compression, creep-induced buckling can be a catastrophic failure mode. That is, collapse can occur on account of creep deformation that causes the structure to be increasingly imperfect. Consider an elastic column under compression, and imagine a plot of compressive load versus midspan deflection perpendicular to the longitudinal axis of the column. For a perfectly straight column, the load-deflection curve will trace the load axis up to the Euler buckling load. For columns with an initial curvature (imperfection), the load-deflection curve will start at zero load with a slight positive deflection. As the load increases, the load-deflection curve will rise, bend over to the right, and follow a state of zero slope where the load deflection values at this point define an unstable state corresponding to that initial imperfection. Similar points in the load-deflection plane exist for other values of initial imperfection. One can anticipate that the locus of all such points is a curve starting at the Euler buckling load and decreasing as a function of deflection. In creep-induced buckling, the structure is initially loaded to a point safely under this instability locus; however, as creep proceeds under constant load, the deflection can increase with time until the locus is reached.

Thermomechanical fatigue (TMF) is another creep-related failure mode. Consider, for example, a service cycle where strain and temperature are cycled between two levels with a hold time at the higher level, all the while being proportional to each other. If the ratio of strain range to temperature range is other than the thermal-expansion coefficient of the material, a stress will be generated when the thermal-expansion strains are exceeded. During the dwell time, some of the stress will relax. After sufficient repetitions, a hysteresis loop in the stress–strain diagram may stabilize; this behavior is analogous to low-cycle fatigue involving plastic deformation where the number of cycles to failure can be significantly fewer than for high-cycle fatigue involving only elastic behavior.

The evaluation of certain types of electrical components (e.g., glass or ceramic insulators) can involve accelerated aging tests. These parts are typically expected to withstand long periods of use with environmental effects (e.g., temperature variations, humidity, and corrosives) having the major degrading influence on how they behave. These materials can deteriorate because of the condition of their surfaces. Small surface cracks can develop that weaken them and allow penetration of materials whose effects further weaken them.

2.6.2 Fatigue Structures are often subjected to fluctuating or oscillatory loads. The behavior of these loaded structures can differ fundamentally from those loaded statically or even dynamically if fatigue considerations are present. Fatigue is a structural behavior that is characterized by four features:

1. reduced strength,
2. reduced ductility,
3. reduced load ranges (minimums and maximums), and
4. reduced number of load repetitions expected in the service life.

The effects of fatigue can occur in widely different materials (e.g., metals, plastics, rubber, and concrete). Each material has some inhomogeneities; these imperfections (e.g., surface cracks, inclusions, voids, and interfaces in composite materials) are the source of fatigue. When a structure has some stress concentrations, the presence of these imperfections gives opportunities for cracks to grow. When the stress concentrations are combined with repeated loads, the resulting effect is to give greater emphasis to these imperfections. Characterizing these imperfections is an important but tedious process. Evaluating a structure (known to have some flaws) in a well-formulated fatigue test will integrate the effects and give insight into how a prototype or actual structure will respond.

Fatigue loads on structures may be cyclic, as in rotating machinery, or random, as in flutter on aircraft wings as given in Bendat and Piersol (1986). These loads may alternate between tension and compression, may increase or decrease around a mean value, and may be uniformly or randomly distributed over a structure. Experience shows that loads alternating about a mean value but *always* in tension or compression produce a certain damage potential; loads alternating from zero to a peak value (in tension or compression) produce a greater damage potential; and loads alternating from tension to compression produce even a greater damage potential. A common way of representing these stresses is through the stress ratio $R = \sigma_{\min}/\sigma_{\max}$; $R = -1$ for equally alternating tensile and compressive stresses, $-1 < R < 0$ for alternating tensile and compressive stresses, and $0 > R > 1$ for alternating tensile stresses. For alternating compressive stresses, R depends on the material (e.g., brittle or ductile) as the presence of any tension field governs the fatigue behavior as reported in the ASM Metals Handbook (1985).

The classic approach in fatigue studies is to generate a series of S–N curves for a specimen or portion of a structure exposed to cyclic loading. The ordinate S is for tensile stress and the abscissa N is for the number of cycles. Each point on the curve indicates the failure of a specimen at the number of cycles corresponding to the constant stress amplitude. These curves (for metals) typically exhibit a decreasing value for the failure condition until a horizontal asymptote is reached with the implication that the fatigue loads corresponding to this level of stress can be endured indefinitely.

Three areas of research have increased our understanding of fatigue loads and their impact on structural testing:

1. the development of relationships between plastic strain in materials and fatigue life,
2. the development of fracture mechanics to enable competent evaluations and assessments of structural designs, and
3. testing capabilities combined with statistically significant test methods, giving better information and data for design purposes.

It is now possible to assess the fatigue life of a structure or component on the basis of crack-growth data and strain-life data, along with the stress–strain relationships for materials. Areas or portions of structures that are "hot spots" known to be subjected to large fluctuating stresses are often isolated and tested separately. Aircraft test laboratories often use many testing machines devoted to fatigue testing of component sections. These include uniaxial (tensile specimens), biaxial (specially designed items, tension–torsion specimens), and triaxial tests.

With the continued development and use of high-strength materials, some composites, and minimum-weight structures, fatigue conditions are more prevalent than ever. Fatigue testing can be essential in the development of any structure that will experience fluctuating loads including structures designed for land transportation systems, aircraft, and railroad use.

Fatigue and fracture mechanics are often linked together. Fatigue may not result in fracture (although degradation is usually measured in this manner). Fracture can occur without fatigue. They are found together in fatigue testing because specimens and components usually fail by fracturing. Occasionally other failure modes are found by fatigue tests, but they are infrequent and do not result in a worst-case or even typical failure condition.

2.7 Fracture-Mechanics Tests and Specimens

Fracture is one of the ways failures occur in materials and mechanical assemblies.

Fracture rarely happens in one cycle of an overload. Fracture most often occurs because of repeated cycles of loading or because stressed materials are subjected to degrading environments (e.g., corrosion). Three basic developed approaches address fracture in materials: linear elastic fracture mechanics (LEFM), elastic-plastic fracture mechanics (EPFM), and fully plastic analysis. Each approach is an approximation of the actions within the material when a crack occurs. Linear theory is the most widely used as it is analogous to relating the stress state in a material or assembly to the tensile properties of the material. When a crack forms and propagates there is some plastic deformation that occurs in and around the crack tip.

The focus in fracture mechanics is on understanding how the generation and propagation of flaws in materials occurs. Three basic regimes of material behavior are relevant to understanding fracture mechanics:

1. at or below the threshold when cracks occur,
2. conditions in which cracks can develop, and
3. conditions in which cracks propagate.

Most materials have some types of microcracks that occur because of inclusions, surface roughness, or heat treatment. With the appropriate conditions of applied stress, microstructure, and environmental influences, microcracks begin to form into a crack. Three developed modes describe the propagation of a crack (opening, shearing, or tearing). The majority of cracks result from actions that cause opening, similar to driving a wedge into the material. The goal of fracture control is to ensure that strength of the material or assembly does not drop below a level safe for use. Cracks must be prevented from growing to a size that allows this to happen. The process of analysis and testing to determine the potential action of cracks and the degradation of an actual material or assembly is called damage tolerance design as described in Broek (1989). Among the items considered are the locations where cracks could develop, analysis and tests to determine the crack growth time, and the strength as a function of the crack size. Alternatively, periodic inspections are made of critical parts in which cracks could develop and reduce the strength of the material or assembly below the level safe for use. The focuses of the analysis and design efforts are on the effects of cracks on strength and the time required for crack growth.

Linear elastic fracture mechanics (LEFM) is based on the release of strain energy stored in the material. Crack propagation is predicted on the basis of the relationship of a material's plain strain fracture toughness (K_{Ic}) and the elastic stress in the vicinity of the crack in the material or assembly. This LEFM approach is often referred to as the defect-tolerant approach. In this approach, a flaw size is assumed to be present or is observed. The number of load cycles required to cause the component or specimen to fail is calculated. Tests for this fatigue-based fracture mechanics focus on two aspects:

1. determining the threshold below which crack growth is not observed (regime 1) and
2. determining the fatigue crack growth rate (ratio of growth to number of cycles) and the alternating (cyclic) stress intensity.

The material's fracture toughness is directly related to the threshold at which crack growth is not observed. The growth rate indicates the number of cycles the material can withstand before its strength drops below a safety level, as given in Rolfe and Barsom (1977) and Broek (1989).

The elastic-plastic fracture-mechanics approach extends the methods developed for linear elastic predictive capabilities into nonlinear elastic behavior. This approach uses refinements in predictions beyond the linear elastic range to measure a material's fracture toughness and tearing resistance, as cited in Rolfe and Barsom (1979).

Tests for a material's fracture toughness can be performed on testing systems capable of applying cyclic forces in a closed-loop configuration through either computers or function generators. Four standard specimens and test procedures have been developed and are defined in ASTM Standard E399. The elastic-plastic fracture-mechanics analysis method uses the crack opening displacement (COD) and the *J* integral. These two methods used in EPFM are defined in ASTM Standard E813 along with the test methods. Both E399 and E813 use bending and C-shaped precracked specimens.

2.8 Pressure Systems and Vessels

Pressures for test purposes are applied through two primary media: liquids and gases. These pressures are in turn transmitted directly or indirectly to a test item. Pressure systems consist primarily of pumps, regulators, intensifiers, accumulators, controls, and safety devices. Repeated cycles of a pump will achieve very high pressures (e.g., 1 GPa). An example pressure system is shown in Fig. 7. Each cycle of a pump produces a small step-function increase in pressure depending on the volume of the pump. Regulators, intensifiers, and accumulators can be installed on the outlet side of the pump. Regulators smooth out the steps in pressure increases. Accumulators store pressurized fluids or gases. An intensifier obtains higher pressures than the pump can deliver.

Control of pressure systems can be through manual valves or through air or electrically operated servo valves or through solenoid-controlled valves. Valve control is also possible with computers and function generators. It is possible for the output of a hydraulic testing machine (the pressure in the hydraulic system) to be the input (low-pressure side) of a pump so that higher pressures could be obtained. Pressure systems and vessels are described in detail in Reese and Kawahara (1993).

The pressure vessels are used in two basic ways:

1. to provide a pressure source for processes, operating and testing systems, and other applications requiring an uninterrupted pressure supply and
2. to contain the pressures applied to test items.

Examples of commercially available pressure sources that have pressure vessels include air compressors and systems using U.S. Department of Transportation (DOT) gas bottles. There are many different types of pressure vessels: two are shown in Fig. 8. On the left side is a vessel with a bolted closure with two ports (not shown) in the head of the vessel. The vessel is sealed by the use of two O-rings. The removable closure permits access to the vessel so test items can be placed inside. The ports are through holes in the closure. The ports are needed for the vessel inlet pressure supply, venting air while filling the vessel, a sealed pass-through for instrumentation, and removal of pressurized fluids or gases on conclusion of the test.

Figure 8 also shows a vessel with an elliptical removable closure (head). This closure is lowered onto a set of O-rings. The closure is tightened by pulling the tapered clamping rings around the vessel circumference using the ratcheting turnbuckles. This clamping action seals the vessel along the O-ring surfaces. This vessel also has ports (not shown) for inlet pressure, bleeding air if a liquid is used for the pressure medium, and pressure measurements. These ports may be in the vessel or closure or both. Both vessels can be equipped with additional sealed ports and electrical connectors that contain the pressure but allow passage of electrical wiring so that instrumented pressure tests can be performed. These sealed ports and connectors permit test items subjected to external pressure to have strain gages installed with the wires leading to the data-acquisition system. Test items are typically suspended from the closures while they are tested. These vessels are often placed below ground or are installed in pits to permit easier personnel access and reduced crane height needed to lower test items into the vessels.

The design and certification of pressure vessels for manned operations come under the guidance of the applicable sections (III and VIII) of the ASME pressure-vessel codes or equivalent requirements. Many commercial suppliers offer fittings, tubing, valves, manifolds, and other equipment needed to build pressure systems. The equipment supplied comes in various operating pressure

ranges, including the very high-pressure ranges in excess of 670 MPa.

In terms of containment, there are two concerns: pressure, and debris from tests in which failure occurred. Normally, a vessel used to contain pressure would not be used as a containment system for failure tests, particularly if debris from a failed test item is expected. Debris could impact the wall of the vessel and initiate cracks and other degradation of the inside surfaces of the vessel. For planned burst tests and proof tests that must be performed remotely, a containment system is needed to protect personnel from possible debris. Some examples of containment systems include:

1. bunkers and pits,
2. blast-proof test cells,
3. underwater operations, and, when all else fails,
4. sufficient distance.

Sufficient distance provides separation of personnel from possible debris. Bunkers, pits, and test cells contain the debris and released pressure by thick walls, soil embankments, and heavy access doors. Underwater operations involve lowering test items into the water and using the water to absorb the energies associated with ejected parts and released pressure.

Certification of pressure systems and vessels usually consists of a pressure test at 1.5 times the design working pressure. Most vessels so designed have much larger margins (typically 4) so that the proof test is very unlikely to cause initiation or propagation of material flaws reducing the pressure capability of the vessel. The major reason for the added safety requirements for pressure vessels is that the stored energies in the pressurizing medium, vessels, and pressure system are typically much greater than in other types of structures, and the potential for damage if ruptured is much greater. Failures of pressure vessels can be dramatic, involving large fragments that can be thrown great distances because of the energy contained. Further, there have been enough failures involving vessels that they require greater consideration in design and certification than other types of structures. Additional procedures are required for systems designed for use above 20 MPa. These certification procedures include detailed structural analyses, material tests results and certifications, certified fabrication procedures with special emphasis on machining, forming, and welding, and testing.

Pressure systems are protected using pressure-relieving devices. A variety of devices are used:

1. burst disks designed to fail at specific pressures,
2. spring-loaded valves that allow passage of fluid or gas when the force induced by the pressure overcomes the preload in the spring, and
3. other types of mechanically operated systems designed to open at or above specific pressures.

These devices should be set, installed, used, and periodically inspected to ensure safe operations involving pressure systems and vessels as described in ASME/ANSI (1988).

The nemesis of pressure systems and vessels is the presence of leaks. Leaks can occur in a myriad of places—welds, seals, connections, fittings, etc. Determining the leak location can be as simple as visually locating the hole or fitting or can require sophisticated techniques (e.g., helium leak detection). A leak can be observed by a drop in pressure during attempts to maintain it constant. Leak rates can be determined by monitoring the drop in pressure over time or by more sophisticated methods involving accurate flow measurements.

Before performing pressure tests, the following assessment should occur.

1. Determine the vessel and/or system to be tested and the test objectives.
2. Perform energy calculations as described in Reese and Kawahara (1993). These energies indicate the levels of protection and the type of facility needed in order to perform the tests safely (e.g., barriers, remote operations, and capability of containment systems).
3. Evaluate options—test using liquids whenever possible to reduce the energy in the pressurizing medium and facilities.
4. For units externally pressurized, provide some type of post-test pressure relief device (valve or removable plug) to vent any pressure accumulated during testing.
5. Check for leaks after the pressure level has been reduced if the test item cannot sustain pressure.
6. Provide other safety measures—personnel access denial, restraints on pressure lines in case of failure of test item, fittings, and proper disposal of test gases and fluids.

2.9 Thermal Systems

Thermal systems for structural tests involve three types of systems: temperature-controlled ovens for steady-state or programmable (variable) temperature conditions, radiant-heat systems for rapid temperature rises and temperature gradients, and burn facilities to create maximum temperatures and durations of fires. The ovens rely primarily on convection, conduction, and radiation as the means of heat transfer to the test item. The radiant-heat and burn facilities rely primarily on radiation as the means of heat transfer.

Temperature-controlled ovens typically operate between −75 and 535 °C (−100 and 1000 °F). They can control temperatures within a few degrees for nearly steady-state conditions. Ovens can also be programmed so that temperature cycles can be applied to test items. These ovens are typically heated with electrical resistance heaters, heat lamps, etc. Ovens can be used by themselves, installed in testing machines surrounding a test item, or placed on test frames and beds. In addition, most ovens can have other conditions introduced such as humidity, salt fog, or other environmental or climatic conditions, as described in Herzfeld (1962) and Reese and Kawahara (1993).

Radiant-heat facilities typically use some type of quartz lamps, which heat up rapidly when electrically activated. These facilities are capable of heat fluxes as large as 1380 kJ/m·s (400 Btu/ft·s) with rise times of 2 or 3 s. The amount of heat needed for a test depends on the test item, on its size and materials of construction including emissivities, and on the design or service requirement that is to be duplicated.

A burn facility involves the combustion of flammable materials, typically hydrocarbons. Various types of burn facilities exist including a chimneylike facility, an open pool, an enclosed pool, and an air-curtain burner. These facilities can have the supplies of air and fuel mixed so that there is an ideal burn (stoichiometric), fuel rich, or air rich. Rich means there is an excess supply of fuel or air in comparison with ideal burn conditions.

A chimney facility is constructed much like an ordinary fireplace with the test item positioned above the point where the fuel and air are combined and ignited. A pool facility consists of a lake or pond of fuel with the test item positioned near or above the surface of the fuel. An enclosed pool is similar except that a barrier surrounds the pool limiting or controlling the amount of air that can combine with the fuel vapor near the surface of the pool, depending on the position of the barrier. The temperatures in these burn facilities range from 760 to 1300 °C with a variation of about ±40 °C. The rate of heat production is limited to about 70–105 kJ/m·s (20–30 Btu/ft·s). The temperatures are determined with strategically placed thermocouples on the test item and in the fire.

2.10 Modal Analyses

The purpose of this type of equipment is to excite a structure to determine its mode shapes and frequencies. The loading conditions must be dynamic so that relative motions are created within the structure or component. Among the types of equipment used are instrumented hammers, vibration exciters, and others that result in forced or constrained displacements. An instrumented hammer consists of an ordinary hammer with a piezoelectric force transducer installed as shown in Fig. 9. The force transducer is calibrated so that the impact force–time history can be measured. The hammer tip is interchangeable so that different frequencies can be excited. With accelerometers and strain gages strategically placed on the test item, the excitation caused by the hammer blow will cause the structure or component to respond dynamically as measured by the transducers (typically accelerometers). Analyses of the data will yield the mode shapes and frequencies as given in Ewins (1985), Kobayashi (1987), and Reese and Kawahara (1993).

The structure can also be excited by an appropriately mounted vibration exciter. Similar instrumentation as with the hammer test would be used to measure structural response. The analysis of the data gives the mode shapes and frequencies. A forced or imposed displacement can also cause a structure to respond. For example, a cantilever beam could be preloaded into a deflected shape. If the preload is transmitted through an explosive bolt or some other type of restraint that can be released rapidly, the structure will respond dynamically at release until the vibrations damp out.

2.11 Inertial Systems (Centrifuges and Spinners)

Centrifuges create uniform acceleration conditions or gradients along a test item. Centrifuges are devices that have a rotating arm attached to a drive mechanism. The in-

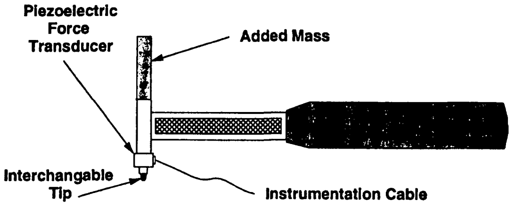

FIG. 9. Instrumented hammer used for modal analyses.

ertial forces are created by the combinations of the radial and tangential accelerations given by

$$a_r = \omega^2 r \tag{1}$$

and

$$a_t = r\alpha, \tag{2}$$

where a_r is the radial acceleration, a_t is the tangential acceleration, ω is the angular velocity, r is the radius to the point measured, and α is the rate of change of angular velocity. For nearly steady-state conditions, a_t is zero, and the inertial force is directly proportional to the mass of the test item and the radial acceleration.

Centrifuges come in a variety of sizes for testing structures and components ranging from a radius of nearly zero to a maximum of about 10 m. The accelerations vary from slightly over one g to more than $2000g$. An example centrifuge used for structural testing is shown in Fig. 10 as described in Reese and Kawahara (1993). This centrifuge has the drive motors located under subflooring in a pit. A containment structure is built around the perimeter of the centrifuge. A dynamic balance compensator is built into the two arms to allow for differences in the calculated balances required during operation. This compensator permits some vertical movement of the support arms while the centrifuge is rotating. The centrifuge also has slip rings so that data acquired during a test can be transmitted to data-acquisition and -recording systems. These slip rings also provide a means to operate test items (e.g., controls, actuators, and electrical systems). Larger centrifuges are usually serviced by an overhead crane.

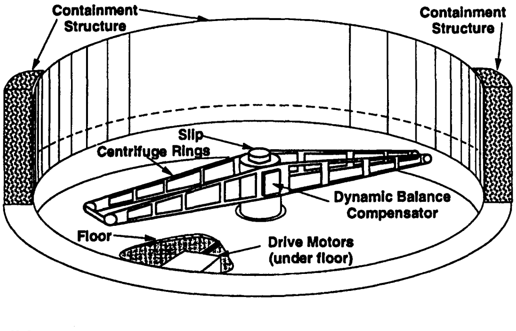

FIG. 10. Centrifuge.

Spinners are usually air-driven turbines placed in a housing. The housing is usually positioned in a sealed pit. The pit can be evacuated so that little or no air resistance is encountered while the spinner is in operation. Test items are attached to the turbine drive motor through fixtures and adapters. Spinners can operate at no-load speeds up to approximately 50 000 rpm. Spin testers are often used to evaluate the performance and operation of high-speed rotating assemblies and systems (e.g., artillery shells, and jet and turbine engine components—blades, compressors, and drive motors).

Among the assumptions made in using centrifuges and spin testers is that the test item will not fail. In order to rotate, centrifuges and spin testers must be dynamically balanced. If failure occurs in the test item, then the dynamic balancing of the arm allowing rotation of the spinner itself is upset when the structure deforms or changes position as it fails. When the dynamic balance of a centrifuge or spinner is upset, there is a danger of damaging bearings, containment systems, slip rings, counter systems, drive system, etc. A few centrifuges have been designed to tolerate ejection of or at least gross displacement of test items. However, this is not the usual case so that centrifuges usually need to be protected from displacement or gross deformation of test items. Among other features that can be incorporated in centrifuges and spinners are temperature chambers and vibration shakers.

2.12 Vibration Systems

Vibration equipment consists of three basic types of exciters: electromagnetic, hydraulic, and mechanical. Examples of each of these vibration test systems are given in Fig. 11. These exciters can produce steady-state, transient, and random vibrations depending on the controls used. Each type of equipment has advantages (e.g., larger frequency ranges) and some disadvantages (e.g., limited sizes for test items) as explained in this section. There are two ways vibration test equipment is used:

1. with items attached directly to the vibration table and shaker and

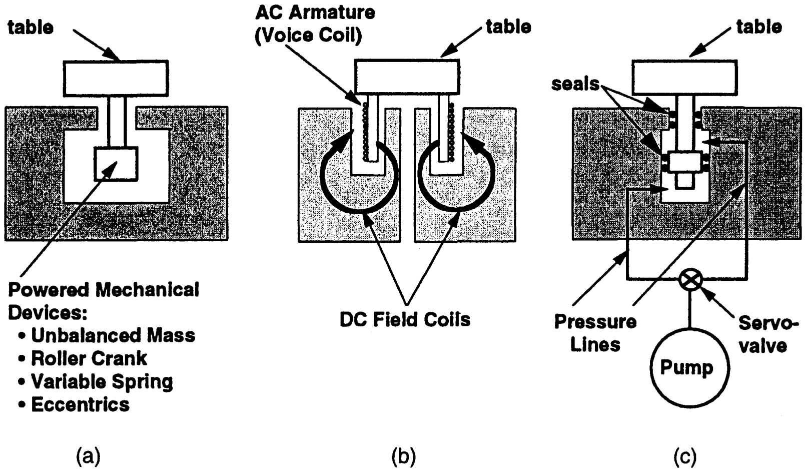

FIG. 11. Vibration testing systems: (a) mechanical, (b) electromagnetic, (c) hydraulic.

2. as an exciter attached to and capable of vibrating large structures such as buildings or bridges.

Test items are usually rigidly attached to a plate or mounting fixture that is connected directly to the shaker. The motion of the shaker is transmitted to the fixture and the attached test item. For test items much larger than the plates or mounting fixtures, portable exciters and driver systems (power sources) have been developed that can be installed at various locations on the structure or test item. Clever placement of these portable shakers can cause vibrations and resonances in the structure as reported in Reese and Kawahara (1993).

The mechanical exciters use cams or a variety of other devices (e.g., roller cranks, variable springs, eccentrics, and unbalanced masses) to induce small varying displacements to the table supporting the test item or directly to the test hardware. The hydraulic systems are similar to a testing machine with the motions of the support or base plate caused by moving the hydraulic fluid rapidly through servo valves as given in Harris (1988).

The electromagnetic exciters move a magnetic-field coil suspended in a driver coil. The driver coil is attached to the shaker support structure through flexures to minimize interactions of the field coil and the support structure. As the magnetic field changes, small displacements are induced in the field coil that cause vibrations in the attached test items. The motion of the field coil is very similar to the voice coil arrangement in a loudspeaker system. Vibrations can also be imposed on structures by acoustic systems, which can operate at 150 dB or more. Many flight structures have requirements to pass acoustic-induced vibrations simulating missile liftoff and engine noise.

Steady-state vibration consists of sinusoidally varying displacements of the plate or mounting fixture. Transient vibration is defined by a sinusoidal excitation multiplied by an exponentially decaying signal. Random vibration is defined by the superposition of many sinusoidal signals with random phase. Examples of these three basic types of acceleration–time histories are given in Fig. 12.

Vibration testing consists of four basic parts:

1. specification of the vibration environment

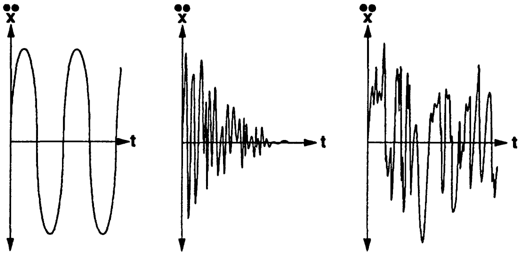

FIG. 12. Acceleration–time histories for vibration environments.

(sine, random, frequencies, magnitudes, and duration),
2. attachment of the test item or structure to the properly selected vibration machine through the use of fixtures and preloading techniques,
3. selection of the diagnostic transducers and their installation at critical and/or informative locations, and
4. performance of the test including the data acquisition, reduction, and analyses.

These four parts depend in varying degrees on the equipment. The input depends on a particular machine and/or laboratory capability. Attachments depend on the basic machine, modifications made to it, and proper fixtures. The diagnostic transducers chosen depend on the data-acquisition and control systems. Analysis of the data depends on the type of data and the computer systems and software available. Vibration-test equipment capabilities can be described in the following manner:

1. The frequency range capability of a shaker decreases with increasing design force capability.
2. Mechanical shakers can only be used for low-frequency tests (up to 100 Hz).
3. Hydraulic shakers can be used up to 2000 Hz.
4. The upper frequency ranges (well above 2000 Hz) can be reached only with electrodynamic shakers, which cover frequencies to 10 000 Hz.
5. The largest forces are delivered by hydraulic shaker systems.
6. Electromagnetic shakers are typically limited in displacement to 25 mm.
7. Hydraulic shakers have more displacement capability than electrodynamic shakers.
8. Mechanical shakers have the most displacement capabilities—about 150 mm.
9. Hydraulic and mechanical shakers perform sinusoidal vibration tests, but the precise control required for complex random or transient wave forms is difficult to achieve. Advances in electronic controls and servo valves will facilitate random-vibration tests on future hydraulic vibration systems.
10. Electromagnetic shakers can produce complex random motions in test items.

2.13 Shock Systems

Shocks can be induced in structures and test hardware by rapid accelerations or decelerations. Decelerations can be produced by dropping the structure or component to be tested onto a stationary target. The resulting velocity change causes a shock loading to the test item. Accelerations can also be produced by placing the structure or component in a type of gun. With a rapid creation of pressure from the burning of propellant or the sudden release of pressurized gases, the structure or component is subjected to a rapid increase in forces causing an acceleration. Shocks can also be produced by preloading a structure into a deflected position and then suddenly releasing the preload as reported in Reese and Kawahara (1993).

Shock testing machines are manufactured by many companies, and many laboratories have designed and built special and general use systems. They basically consist of an elevating table for mounting the test item. The table can move to a position above a contact surface. A shock loading is produced when the table is dropped along guide rails onto the contact surface. The shock pulse can be tailored according to the shock absorbing materials used on the contact surfaces, the velocity change produced, and the masses of the table and the test item. Greater velocities can be achieved if long elastic cords attached to the base of the machine are tensioned to provide a pulldown force to the table and test item.

An example of a shock test machine is shown in Fig. 13. The test item is located on the mounting plate. The lifting winch is used to raise the mounting plate to an elevated position. The mounting plate impacts onto a programmer of specially selected materials (e.g., felt pads and honeycomb) designed to supply a certain shock pulse (acceleration time history) to the component.

Gas guns, horizontal actuators, and other similar devices supply the sudden release of energy (typically pressure), which is captured behind a movable attachment system (e.g., piston) and test item. The release of the stored pressure causes rapid movement of the piston. The resulting acceleration can produce the desired shock depending on its rise time. The moving piston and test item can also be impacted into a stationary target,

a movable mass, or other type of target depending on the type of shock pulse needed. An example of a gas gun is shown in Fig. 14. In this example the test item is attached directly to the piston. The shock pulse experienced by the test item is the same as that of the piston.

Shock tests are also performed using drop towers and cable suspension systems. A shock testing system used for large structures is shown in Fig. 15. This facility consists of a cable stretched between two hills or towers. An instrumented structure to be tested (shown in greatly exaggerated size) is raised toward the horizontal cables. The instrumentation cable travels with the test item. The test item can contain data-recording systems that can be recovered after the test, or it can telemeter data to a receiving station during the test. The left tower also shows a cantilevered section that has a target at its base.

The test item is typically allowed to fall freely either from the cables or from the drop tower. The disadvantage associated with free fall is that the test item may be acted on by lateral aerodynamic loads depending on the height of the tower and the prevailing wind conditions. Shock tests often employ diagnostic high-speed photometric coverage directed to a specific impact location, and these lateral loads can cause the test item to deviate from its course to the target. The test item can also be attached to two cables (not shown) that are located near the impact point. These director cables guide the test item to a predetermined location on the target in a similar manner to the guide columns in a shock machine. The impact velocity will be reduced slightly in this type of directed free fall because of frictional forces between the vertical cables and the attachment guides. Release systems (e.g., explosive bolts that fracture on detonation of a small directed explosive charge) allow the test item to fall freely a short distance prior to impact. The use of release systems prevents unwanted interactions among the guide cables, instrumentation lines, and the test item during impact, as reported in Reese and Kawahara (1993).

Impact velocities can be increased using

large elastic cords that will pull the test unit toward the target. The director cables also run through pulleys near the target. The ends of these director cables could be attached to a rocket sled. This sled would travel along a horizontal path away from the target area. The acceleration time history of the rocket sled could be designed to provide the tension force in the cable needed to pull the test item to the target at the additional desired velocity without cable whip or overload. The test item would also again be released (e.g., explosive cutters) from these guide cables to permit free fall into the target at or very near the desired location for camera coverage. The velocities achieved in these free-fall assisted tests are limited only by practical limits of height, elastic cord forces, or the accelerations delivered by a rocket sled.

Shocks can also be supplied by rocket-sled track systems—a sort of open-air gas gun. This type of loading system produces accelerations to test items attached to rocket sleds. The sleds are accelerated down a single- or dual-rail track by the ignition of rocket engines. Velocities of 1500 m/s can be achieved on tracks as short as 1500 m. The resulting shock pulses can be tailored by attaching the test item to the rocket sled and experiencing the resulting acceleration time history when the sled moves along the track. Shock can also be attained by impacting the sled into an object. Alternatively, the test item can be ejected from the sled after it has reached the desired velocity and then impacted into a target or slowed by deploying a parachute. Shock loads on a test item can alternatively be achieved by accelerating the target into the item. This approach of a moving target allows the test item to be hard wired, which usually aids instrumentation and data acquisition. This "reverse ballistic" technique was developed by Sandia National Laboratories, as described in Reese and Kawahara (1993). The purpose of these shock-generation systems is to impart enough energy or velocity change to the test item to expose it to the required or representative service, proof, or destructive conditions.

2.14 Hardness Tests and Equipment

The hardness of materials is largely a surface phenomenon as influenced by work hardening, yield strength, modulus of elasticity, and grain structures. The tests for hardness are comparative and have their basis in satisfying a need for some convenient measure to evaluate material resistance to scratching, wear, abrasion, and indentation. A hardness test can be used to grade material samples or lots and to provide evidence of quality control. Four hardness tests have been developed and continue to be used: Brinell, Rockwell, Vickers, and Shore scleroscope, as described in the ASTM Standards (current editions). The first three tests are made with indentation techniques while the Shore scleroscope uses the rebound height of a small hammer. The Knoop hardness test system has also been used, and relationships to these four enduring hardness tests are given in ASM Metals Handbook (1985) with primary applications to microhardness measurements. An ultrasonic hardness test is also available.

The indentation techniques use various types of indentors (e.g., balls and pyramids) that are placed in contact with the material surface. A force is applied, and a small permanent deformation occurs in the material surface. Because the indentations are small and usually do not degrade the material performance, these hardness tests including the Shore scleroscope are considered nondestructive. However, hardness measurements can be a detrimental influence on the material surface [e.g., hardness measurements made at the root (minor) diameter of a threaded fastener] where a discontinuity in the form of an indentation is made in a potentially high-stress area of a fastener. Sufficient use has been made of hardness tests so that the measurements made using the different approaches can be compared as given in the ASM Metals Handbook (1985) and the ASTM Standards (current editions). Table 2 summarizes some of the important features of hardness test equipment and practices, as given in Table 3 in the Hardness Testing chapter of the ASM Metals Handbook (1985).

A durometer is an instrument used to measure the hardness of rubber and plastics. Several types of durometers are available with only two (types A and D) conforming to ASTM Standard D2240 ("Indentation Hardness of Rubber and Plastic by Means of a Durometer"). A durometer operates similarly to a hardness tester in that the indentor is brought into surface contact, and then a force is applied and the reading taken using the built-in scale. A major source of discrepancies in durometer tests is the speed at which the durometer indentor is applied to the test item.

Hardness tests of all types need to be conducted on clean flat surfaces. The indentors need to be aligned at right angles to the surface. Several measurements will likely be needed to obtain a statistically significant hardness evaluation. Individual measurements need to be taken far enough from other measurements so there is no interference among them.

3. HAZARDS INVOLVED IN MECHANICAL TESTING

Mechanical and structural tests are often destructive. Protection of test personnel and testing equipment is important. Hazards that need to be considered are

1. the sudden releases of large forces and energies, shrapnel and other debris, and test fixtures that can occur in each destructive test;
2. the many pinch points and related hazards in working with test items and the fixtures, with particular caution required when performing disassembly and removal of damaged, destructively tested hardware;
3. the mechanical gears, electric motors, hydraulic lines, and lasers in proximity to test personnel;
4. the sudden release of high-pressure hydraulic fluids, liquids, or gases;
5. the lifting and rigging of heavy items into and out of the test spaces;
6. the congested spaces in and around the

Table 2. Comparisons of hardness test techniques and test equipment.

Comparison	Brinell	Rockwell	Vickers	Shore scleroscope
Indentor shape	Metallic ball (10 or 2.5 mm)	120° diamond cone 1.6 to 12 mm in diameter	Square-based pyramid with face angles of 136°	Diamond-tipped hammer
Measurements	Applied force/ diameter of indentation	Combination of specific penetrator and hardness scale (15 options)	Applied force and diagonal of indentation	Height of hammer on rebound
Applied force	100 kg$_f$ to 3000 kg$_f$	3 kg$_f$ to 150 kg$_f$	1–120 kg$_f$	2.4×10^{-3} kg from 250 mm
Applications	Large forgings and castings	Forgings to finished surfaces of parts	Fine finished surfaces, thin specimens	Fine finished surfaces, thin specimens

equipment with their associated trip hazards; and
7. the noise associated with equipment operation and test-item failure.

GLOSSARY

Bourdon Tube: A hollow tube that, when pressurized, deforms with repeatable accuracy and, when calibrated, accurately converts the deformed shape into measurements of applied pressures.

Fixtures: The mechanical parts used for attachment of items to mechanical test equipment.

Hardness: Resistance to indentation.

High-Cycle Fatigue: Fatigue involving only elastic behavior of the material.

Loads: The broad category of applied forces, torques, pressures, thermal effects, energy deposition, shock, vibrations, and other excitations that are simulated in mechanical or structural testing.

Low-Cycle Fatigue: A reduced number of cycles to failure because plastic deformation is present (opposed to **High-Cycle Fatigue**).

Photometrics: Descriptive photographic or video records of tests, designed to capture motion and displacement of test items.

Pressure Intensifier: A mechanical system used to increase pressure.

Pressure Regulator: A mechanical system used to control the flow of pressurized liquids or gases.

Servo Hydraulic: The operation and control of a testing machine through the use of electronically controlled servo valves acting on hydraulic cylinders capable of producing motion in two directions.

Slip Ring: Rotating shaft or disk containing a continuous electrical conductor attached to its surface.

Structural Testing: The work devoted to the understanding of how structural systems respond to the conditions imposed upon them.

Whiffle Trees: Loading fixtures used to simulate aerodynamic or distributed forces; the tree is a small beam loaded at each end and at the middle. These trees are typically used in series.

INTRODUCTION

The measurement of blood pressure, the determination of the characteristics of a transistor, or the flight test of an airplane are all procedures that can be called nondestructive testing (NDT), nondestructive evaluation (NDE), or nondestructive inspection (NDI). While these terms are certainly appropriate to such medical and other test procedures, it has become the practice to use them only to refer to techniques that deal with the detection of defects, or flaws, in mechanical structures. Examples are cracks, inclusions, and cavities, or the undesirable change in microstructural parameters of a material. NDT refers to the general method of finding such flaws without damaging the structure that is being examined; NDI refers to the actual testing; and NDE refers to the inspection procedure, a description of what was found, and an evaluation of possible results. For simplicity, in the following text only NDT is used.

Although some costs are involved in carrying out NDT, routine NDT of newly manufactured products has generally been found to be a desirable practice, in terms of both cost and reputation of reliability. NDT is also very important for equipment that operates over an extended period of time, for in the parts of a unit that are under constant or repeated stress there is always the possibility that so-called fatigue cracks can develop. Once formed, a crack can grow until a fracture occurs, with failure not only of the damaged part but, quite possibly, of the entire unit of which it is a component. To prevent such catastrophic failures, it has become the practice in some industries to carry out periodic NDT inspections, even though it means shutting down the operation of a unit for a period of time while the inspections are in progress. Indeed, the usefulness of periodic NDT was demonstrated in a recent survey of electric-power–generating stations in the United States, where it was found that periodic inspections carried out over a 15-year period had reduced expensive failures in these plants considerably from those that occurred before these procedures had become general practice.

The following text describes a number of different NDT procedures. Their aim is to determine the presence of flaws within or on the surface of a structure and, if any exist, their locations and descriptions. The techniques described deal chiefly with the detection of mechanical flaws. Not covered, therefore, are such topics as chemical analyses, measurement of tear strengths of materials, or such specialized topics as determination of concentration and energy levels of impurities in semiconductors.

Among the various NDT techniques, the following stand out as being most widely applied:

1. visual inspection,
2. liquid-penetrant inspection,
3. magnetic-particle inspection and leakage-field measurement,
4. radiographic NDT,
5. ultrasonic NDT,
6. eddy-current testing, and
7. acoustic-emission testing.

These techniques are covered in some detail in Secs. 1 through 7.

In addition, at least 30 other NDT procedures exist. Some of these are quite specialized. Others have been demonstrated in the laboratory but have not yet found wide application. Brief descriptions of these methods are given in Sec. 8.

The reader who would like more detailed information on nondestructive testing procedures than it is possible to present here may be interested in the *Nondestructive Testing Handbook*. This eight-volume set of books of the American Society of Metals (McMaster, 1982a,b) and the American Society for Nondestructive Testing (McIntire and McMaster, 1986; McIntire, 1985, 1987, 1989, 1991; McIntire and Moore, 1993) treats both theory and test procedures.

Finally, while the goals of NDT are to locate and characterize flaws and details of internal structure, in some cases the goal also is to use NDT results for estimating the time to failure, i.e., the interval from the time of the NDT procedure to the instant of failure of the component or structure. In many cases this is a rather difficult task, for it depends not only on the presence of a flaw but also on its size and location, the material, and the stresses to which the component is subjected. Nevertheless, a considerable amount of progress in such prediction methods has been made in recent years. The techniques that have been and are continuing to be developed for carrying out such predictions bear the name fracture mechanics (Hellan, 1984; Mitchell and Landgraf, 1992; Gdoutos, 1993).

1. VISUAL INSPECTION

Although the oldest method of inspection, visual inspection is still generally the first method of examining an object for deviations in shape or for surface faults. However, it is a very subjective method, for the ability to detect such surface faults as small cracks by simple visual inspection is very dependent on the person performing the inspection. It is for this reason that several other techniques of detecting surface cracks have evolved.

Well-known instruments that aid in visual inspection are the ordinary magnifying glass and the microscope. Somewhat less familiar is the borescope, which permits inspection of the inside surface of tubes, such as the cylinder of an automobile engine.

Two types of borescopes are in use. The rigid borescope is simply a small-diameter telescope, in which the image is transmitted toward and in front of the eyepiece by a series of lenses or a single solid fiber with a graded index of refraction. A focusing ring at the eyepiece allows fine focusing. A small lamp in the region of the eyepiece, whose light is transmitted to the distal end either through the lenses or, preferably, through a separate fiber-optic light guide, supplies the illumination for the area being observed. If desired, a mirror or prism at the distal end converts the instrument to a periscope, for viewing surfaces parallel to the borescope.

A more versatile instrument for visual observation of surfaces difficult to access is the fiber-optic borescope. This is a flexible unit that can be several meters in length. It has two sets of fiber-optic light guides between its eyepiece end and the distal end. One of these merely transmits the light from a lamp to the area being examined. The other one is a bundle consisting of many fibers that are precisely aligned to maintain the same relative positions over their entire length. Both ends of this bundle are cut flat and highly polished. An objective lens, whose position is remotely adjustable, is located between the fibers and the area under examination, so as to project an image of this area onto the distal end's surface of the fiber bundle. This divides the image into an array of pixels whose light is transmitted through the fibers to the eyepiece end, to form an image of the viewed area at the ends of the fibers. A lens placed between the fiber ends and the viewing port, with location adjustable to compensate for differences in the eyes of observers, permits viewing of an in-focus image of the area that is being examined.

2. LIQUID-PENETRANT INSPECTION

In this simple visual method of finding surface cracks or regions of porosity, the flaws are highlighted by the use of either a brightly colored liquid or a liquid that fluoresces when illuminated with ultraviolet light. The technique can be applied to virtually all kinds of materials, although its effectiveness is reduced by surface roughness or porosity. The technique is as follows:

1. The surface to be examined is cleaned and allowed to dry. The method of cleaning may include both mechanical and chemical means to remove oil, grease, oxides, and other deposits.
2. The surface is covered with the penetrant, i.e., with the liquid that contains the dye or fluorescent material.
3. After sufficient time has been allowed for penetration of the liquid into cracks or pores, the liquid that has covered the surface is removed, generally with a water spray.
4. A "developer" is applied. This is generally a very fine chalk powder that can be wetted by the penetrant liquid.
5. Around 10–30 min are allowed for the developer to draw the colored or fluorescent liquid out of the cracks or pores. The locations of these flaws are now visible or, in the case of a fluorescent penetrant, can be made visible with ultraviolet light.

Although the highlighting of faults provides a clear advantage over ordinary visual inspection, the method is still somewhat subjective. The fact that the method is not instantaneous may also be a drawback in some cases. Nevertheless, liquid-penetrant inspection is a very popular NDT technique of finding faults that penetrate the surface.

A variation of the method is the use of a fluid with suspended colored or fluorescent particles, used for locating defects in porous surfaces of materials such as unfired dried clay, certain fired ceramics, concrete, some powdered metals, carbon, and partially sintered tungsten and titanium carbide (McGonnagle, 1966). In another variation a surface is covered with a liquid containing a radioactive material, and photographic film is placed over the surface. When developed, the film shows the location of the pores in the surface.

3. MAGNETIC-PARTICLE INSPECTION OR LEAKAGE-FIELD MEASUREMENT

Magnetic nondestructive testing generally deals with the inspection of components constructed of ferromagnetic materials, such as iron and steel, although it could also be applied to ferrimagnetic materials, such as ferrites. These magnetic inspections aim either at finding and evaluating surface or subsurface cracks in a component or at finding possible differences in the magnetic material from the intended composition or microstructure. Methods of finding cracks are the very popular NDT technique of magnetic-particle inspection or an alternative method of leakage-field measurement. Both are treated below. A third technique that deals with magnetic effects, Barkhausen-noise analysis, yields microstructural information. It is briefly described in Sec. 8.

3.1 Magnetic-Particle Inspection

The magnetic-particle method of finding cracks on or just below a surface of ferromagnetic material is based on the principle that a discontinuity in a magnetized material will cause leakage magnetic fields, which will attract and hold fine iron particles.

In discussing magnetic fields that exist in or around materials, it is sometimes useful to recall that dc magnetic fields exist because of the presence of electric currents. Within a magnetic material these electric currents will actually be elemental circulating currents at the atomic level, i.e., elemental magnetic dipole moments, which can also be pictured as elemental bar magnets. For a steel bar these elemental dipole magnets are found to be organized into so-called "domains," i.e., small regions within which the dipoles are parallel to each other. In the absence of presently or previously applied magnetic-field intensity, the domains are randomly oriented, so that no net dipole moment exists. When a coil of wire is wrapped around the bar and an electric current is caused to flow through the wire and this current is gradually increased, more and more of the domains orient themselves parallel to the axis of the bar. To specify magnitude and direction of the density of these oriented magnetic dipoles, it is appropriate to define a vector quantity **M**, the magnetic dipole density, with units of amperes per meter. **M** is generally called the "magnetization."

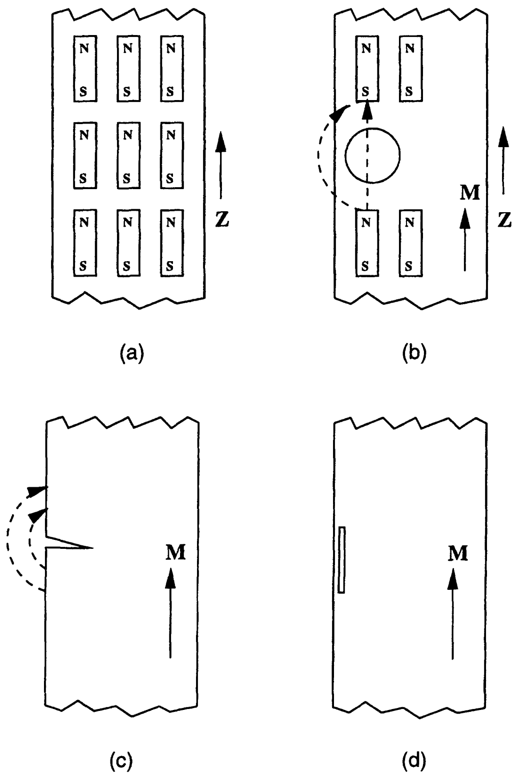

FIG. 1. Detection of surface and shallow subsurface cracks in magnetized ferromagnetic materials. (a) Aligned magnetic dipoles in bar without flaws. (b) Presence of cylindrical hole causes leakage of magnetic-field lines to outside of bar. (c) Surface crack normal to the direction of **M**. (d) Narrow crack parallel to **M**.

We now consider a bar of steel that is uniformly magnetized so that the dipole moments, and therefore **M**, point in the z direction, as in Fig. 1(a). Here, since each elemental south pole is adjacent to an elemental north pole, as shown in Fig. 1(a), there is no magnetic field external to the bar. Consequently, if small iron particles were blown from the left toward the bar, there would be no force to attract and hold them. Let us now suppose that a cylindrical hole were to exist near the edge of the bar, as in Fig. 1(b). The continuous north pole–south pole structure is now interrupted, leaving poles dangling at the hole. Since each of these poles acts as a source or sink of a magnetic field, the magnetic field in the hole is now different from that in the solid piece. Moreover, as seen in Fig. 1(b), there is now a curvature of magnetic-field lines within the bar, with a "leakage" magnetic field that reaches outside the bar. If any small iron particles were to be blown toward the bar now, or if the bar were immersed in a liquid that had iron particles suspended in it, this magnetic field would attract them and they would stick to the bar. If a surface crack normal to the direction of **M** were to exist in a magnetized bar, as in Fig. 1(c), the stray magnetic fields would again attract any iron particles and keep them stuck to the bar.

It is seen and borne out by analysis that a surface or near-surface crack normal to the direction of magnetization, as in Fig. 1(c), produces a leakage magnetic field that is readily detected. On the other hand, a narrow crack that runs parallel to **M**, as in Fig. 1(d), has very little external leakage field. Consequently, to detect such a crack or, in general, a crack oriented in an arbitrary direction, it is necessary to perform three tests, with the unit being tested successively magnetized in three orthogonal directions.

Actually, in most cases only two tests are necessary. An example is the section of steel pipe sketched in Fig. 2(a), with surface cracks A and B. Here current flowing through a wire on the axis of the pipe, as in Fig. 2(b), will generate a circumferential magnetization that will create appreciable external leakage fields for crack A and only negligible fields for crack B, thereby permitting detection of crack A. The converse is true for Fig. 2(c), where the longitudinal magnetization in the pipe will allow detection of crack B.

The techniques that are used for generating the magnetic fields depend on the size and configuration of the components to be tested. In the configurations of Fig. 2 the magnetizing currents flow through auxiliary wires. In some situations the current used to magnetize a unit under test can be caused to flow through the unit itself. Both dc and ac currents, as well as rectified ac, will generate magnetic fields that will attract and hold magnetic particles. In some cases it is possible to use ac polyphase methods that create rotating magnetic fields, thereby obviating the need for two or more test setups.

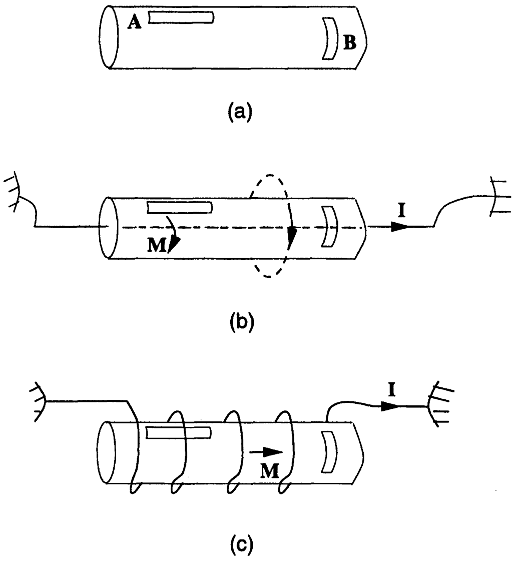

FIG. 2. Detection of cracks in a steel pipe. (a) Pipe with crack A parallel to axis and with circumferentially oriented crack B. (b) Axial current generates circumferential field and magnetization, thereby allowing detection of crack A. (c) Solenoidal current generates axial field and magnetization, thereby allowing detection of crack B.

For most steels, the finest crack widths observed by this magnetic-particle technique are of the order of 10 μm (Betz, 1967), although detection of a 1-μm crack in carburized steel has been reported (McIntire, 1989). The ability to detect subsurface flaws is a function of their shape, size, and orientation. Using dc magnetizing currents, detection depths of the order of 3 to 7 mm are reported possible, while the practical depth limit with ac magnetization is estimated to be less than 1 mm (Hull and John, 1988).

When a material has a high remanence, so that it stays magnetized after a dc current is switched off, the inspection can sometimes be carried out by using only this remanent magnetization. Known as the "residual method," this has the advantage that the test may be performed without the physical presence of the magnetizing equipment. However, the sensitivities in the residual method are generally lower than those achieved when magnetizing current is used.

The magnetic field resulting from any remanent magnetization after either type of inspection has been carried out could interfere with subsequent operations, such as arc welding or the use of magnetically sensitive instruments. It could also attract stray iron particles or chips that could damage such surface-sensitive components as bearing raceways. Moreover, the remanent magnetization could interfere with the electrical operation of a unit. It is therefore necessary to demagnetize the test piece after the NDT procedure.

A standard method of demagnetization is to subject the magnetized piece to a time-varying, gradually decreasing magnetic-field intensity by applying an ac voltage to a coil surrounding the magnetized component while gradually decreasing the amplitude of this voltage to zero. If the initial magnetization was due to an applied dc current, it may be necessary to carry out the demagnetization process by a combination of applying a dc current and the use of the ac demagnetizing technique (Hull and John, 1988).

In practice, the magnetic particles used to mark locations where leakage magnetic fields exist are usually of ferromagnetic material of low remanence, so that they do not adhere to the components under test because of their own magnetization. Both dry application of particles or particles in liquid suspension are in use. To make them highly visible, it is the practice to use particles that are either colored or coated with a material that will fluoresce when illuminated with ultraviolet light.

Since magnetic-particle inspection is an inexpensive and sensitive method of finding surface or near-surface cracks, it is widely used. Its chief drawbacks are these:

1. It is applicable only to ferromagnetic or ferrimagnetic materials.
2. Tests with at least two orientations of magnetization, or a polyphase system, are required.
3. To test large components, very large currents may be required to generate the necessary magnetizations.
4. Although relatively simple, complete success depends on the skill and experience of the person performing the test.

3.2 Magnetic-Field Measurement

While the magnetic-particle method is the preferred method of finding leakage fields that are due to flaws at or near the surface of ferromagnetic materials, these fields may also be discovered by direct measurement. Among the instruments that have been used for such sensitive magnetic-field measurements are

1. moving coil magnetometer—essentially a small rotating coil ac or dc generator;
2. Hall-effect probe—a semiconductor chip in which an electric field transverse to the direction of a drift current is developed because of the deflection of carriers by the magnetic field;
3. flux gate magnetometer—a sensitive instrument in which an ac-driven ferromagnetic bridge circuit develops a second-harmonic voltage whose amplitude is determined by the magnetic field in which it is located; and
4. magnetic tape—magnetic recording tape placed into region where field is to be measured, to be scanned after removal by magnetic-tape reader, to reveal field distribution.

4. RADIOGRAPHIC NDT

Radiographic NDT, also called radiology, uses x rays or gamma rays—electromagnetic waves whose wavelength is of the order of 1 Å or smaller—to penetrate materials opaque to visible radiation, to find flaws, and to map internal structure of bodies. As one of the oldest NDT methods, dating back to Roentgen's discovery of x rays in 1895, it has been popular since the late 1930s and remains as one of the most frequently used NDT techniques. This is despite the well-known fact that both x rays and gamma rays are ionizing radiation and their use requires proper protection for the person performing this type of NDT, either by appropriate shielding or by operation of sensing and recording instruments from a safe distance.

The wavelengths of x rays and gamma rays used for NDT are approximately in the same range of the spectrum. It is the practice to refer to the broadband radiation generated by high-velocity electrons impacting on metal surfaces as "x rays" and to the line spectrum radiation emitted by radioactive materials as "gamma rays."

4.1 Principle of Operation

Radiographic NDT is based on the facts that x rays and gamma rays travel through materials in straight-line paths and that the intensity of the radiation in passing through matter decays as $I = I_0 \exp(-\mu x)$. Here I_0 is the intensity at the beginning of the path, I is the intensity after passing through path length x, and μ is an attenuation constant that depends on the material.

It is the materials-dependent quantity μ that is the key to obtaining information about the internal structure of a test piece. For if a broad beam of x rays or gamma rays is sent through this test piece, any gaps or irregularities within the structure represent deviations in μ from that of the rest of the body and therefore produce local changes of the radiation intensity in the area of the beam as it exits the structure. Irregularities within the body are found by sensing and displaying the spatial distribution of radiation intensity within the beam area.

An example is seen in Fig. 3. In Fig. 3(a) an x-ray beam is directed to enter a metal bar that contains an inclusion, a small po-

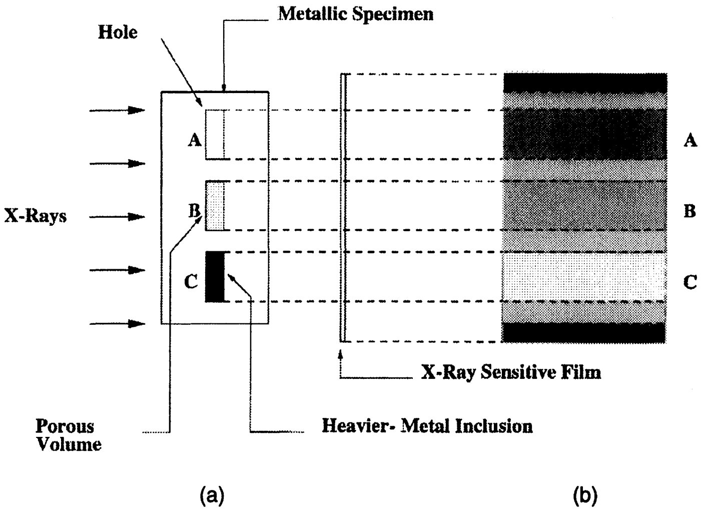

FIG. 3. Principle of radiography. (a) Side view of x rays entering a metallic block that has several regions extending perpendicularly to the plane of the paper throughout the specimen: Region A, a hole; region B, a porous volume; region C, an inclusion of metal of higher density than that of the block. (b) The various shades of gray resulting on the developed x-ray film.

rous volume, and a hole. A sketch of the relative intensity of the radiation on exit from this test piece is seen in Fig. 3(b). When a strip of photographic film sensitive to exposure by x rays is placed so that its plane is perpendicular to the beam, a latent image forms on this film. After development, the degree of "blackness" of a spot in the distribution of varying transparency of the film indicates the relative amount of radiation per unit area that has reached this spot. An experienced observer can conclude from this film strip that region A contains a hole, that there is a shallower hole or a porous volume in region B, and that an irregularity of some sort exists in region C.

Two points are evident in this NDT technique:

1. Accessibility to opposite sides of the test piece is required.
2. The developed film is essentially a shadowgraph that depicts the relative transparency to the radiation along the straight-line paths followed by the radiation. The "blackness" of a spot on the film is therefore an integrated response of the entire path traveled along the straight-line path of the radiation reaching this spot.

For the sake of demonstrating the basic idea of radiography, the rays representing the x-ray beam of Fig. 3 were drawn parallel. While a parallel x-ray (or gamma-ray) beam can be approximated by the use of a large separation between a physically small radiation source and the test piece, a more efficient method uses a small source, with subsequent data manipulation that takes beam divergence into account.

In the example of Fig. 3 the final step was interpretation of a pattern displayed on photographic film. Other types of visual display media are also in use and are mentioned later in this article. In all cases, though, radiographic NDT is based on interpretation of two-dimensional displays.

4.2 Three-Dimensional Information

Although a two-dimensional display such as that of Fig. 3(b) may be sufficient in many cases, it lacks information on the depth distribution of flaws or irregularities within the test piece. Additional information, though not a complete depth distribution, can be obtained by repeating the procedure with the test piece rotated by, say, 90° with respect to the first exposure. Consequently, for most cases one or two images can provide sufficient information about the integrity of the test piece.

For more detailed information, the operation of Fig. 3 can be repeated, with the test piece rotated with respect to the incoming radiation to *several* different angular positions. If the distributions of intensity at the film plane for each orientation are then used in a mathematical inversion process, detailed depth information of the internal structure can be obtained (Radon, 1917). One example of this technique is computer-aided tomography, well known in medical technology as "CAT scan," which pictures two-dimensional mass distributions within what are essentially slices of the scanned material (Kuhl and Edwards, 1963; Hounsfield, 1973).

4.3 Unsharpness, Contrast, Sensitivity

4.3.1 Unsharpness The detection of flaws of minute size or the accurate representation of internal structure requires high spatial resolution. Because it is generally not possible to focus x rays or gamma rays, it is important to have the source of the radiation as small as possible. This requirement is illustrated in Fig. 4, where the diameter of an aperture in a thin plate of material that transmits no x rays is to be determined by measurement of the diameter of the display on a photographic film.

Because of the short wavelengths, spatial uncertainty in the image due to diffraction effects are negligible, so that for the point source of Fig. 4(a), diameter d is almost precisely given by $d = (o/i)\ D$.

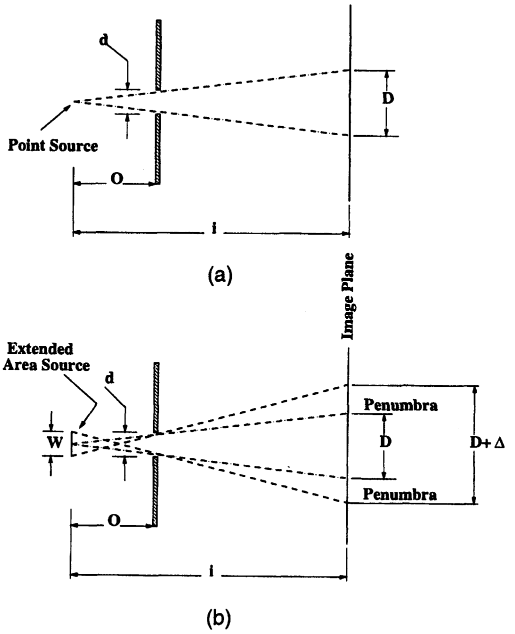

FIG. 4. Unsharpness caused by an x-ray source of extended area. (a) Point source causes illuminated region of precise width D. (b) Source of extended area produces a penumbra region of unsharpness.

In Fig. 4(b), on the other hand, the width W of the source creates a penumbra, or partial shadow region, which causes a blurriness in the image and therefore an uncertainty in the determination of dimensions and location and width of the aperture. In the language of radiographic NDT, this uncertainty is generally called the "unsharpness." Here this unsharpness is due to the size of the radiation source. It may also have other causes and is an important consideration in the design of a radiographic NDT system.

4.3.2 Contrast An example of the importance of the consideration of "contrast" is the following question: Since local changes in thickness of a specimen reflect as changes in the blackness of the film and should therefore be recognized visually by the contrast between various portions of the display on the film, what is the minimum change in thickness Δx that can be detected?

An estimate can be made by calculating a quantity called the "subject contrast," which is used to refer to the fractional change in the radiation transmitted because of a change in thickness or the presence of a foreign body within the test piece. Based on the expression $I = I_0 \exp(-\mu x)$, mentioned in Sec. 4.1, the subject contrast for a small change in thickness Δx is approximately $\mu \Delta x$. Similarly, if the radiation passes through a foreign body within the test piece whose thickness is x_0 and whose attenuation constant is $\mu + \Delta\mu$, where $\Delta\mu$ is considerably smaller than μ, the subject contrast is approximately $x_0 \Delta\mu$.

The calculation of subject contrast yields an optimistic estimate, for the actual contrast in a display depends on a number of factors, including fogging of the film by "noise" background caused by scattering of the radiation by the test piece and the characteristics of the film or other display system. More general expressions exist that also take these other factors into account. Some techniques to increase contrast have been devised and are mentioned in a later section.

On the basis of practical experience, it has been found that a gap that is less than 2% of the overall thickness of an item under test is difficult to observe (Cartz, 1995). A fine crack will therefore probably not be observed if the plane of the crack is perpendicular to the path of the radiation.

4.3.3 Sensitivity The term "radiographic sensitivity" refers to the smallest detail that can be seen on a radiograph, or the ease with which small details can be detected. It is a quantity that is somewhat subjective, for it refers to detail resolvability, not to spatial resolution. An example is the case of a small flaw that is an inclusion whose density is quite different from that of the region surrounding it. If this density difference is large, the flaw may yet be discovered, even if it is smaller than the spatial resolution of the system. A flaw whose density is quite close to that of the rest of the test piece would need to be considerably larger in order to be detected.

4.4 Radiation Wavelengths or Photon Energies Required

To produce a shadowgraph image within a reasonable time, the radiation incident on a test piece should be of readily achievable intensity. It also should have a wavelength that allows penetration, but with sufficient attenuation to permit the detection and imaging of incremental structural irregularities, such as a gap or an inclusion.

A quantity that has been used to determine the appropriate wavelength of the radiation required for a particular situation is the "half-value layer" (HVL), i.e., the thickness of material that reduces radiation intensity by one-half. Values of HVLs as a function of wavelength λ for different materials have been measured and are published. Instead of listing these as a function of λ, however, they are often listed as a function of the voltage V_a applied to the electron tube used to generate the radiation, since a photon of the shortest wavelength (and therefore of highest energy) in an x-ray beam so generated has wavelength $\lambda_0 = ch/eV_a$, where c is the velocity of light, h is Planck's constant, and e is the electronic charge.

As examples of the magnitudes involved, it is found that HVL values for concrete are 0.51 cm for $V_a = 50$ kV and 4.5 cm for 1 MV, whereas for steel and $V_a = 1$MV, HVL = 1.6 cm (Bryant, 1985). These numbers indicate that high voltages are required to generate the x rays for NDT of solid bodies. Thus, steel structures thicker than a few centimeters require radiation of shorter wavelengths, corresponding to photon energies greater than 1 MeV.

The maximum thickness of material that can be examined depends also on the method of detection and imaging. It is found that for typical commercial equipment, steel specimens examined with 1-MV x-ray equipment can have maximum thickness of 16 cm (Halmshaw, 1982).

Since the objective of radiographic NDT is to obtain an image that displays sufficient contrast for finding flaws or showing internal structure, the choice of energy of the radiation to be used depends on both the material and its thickness. In general, it has been found that a radiograph should be made with radiation of the longest wavelengths, i.e., the lowest photon energies, that will transmit adequate radiation intensities to the detecting medium, because long wavelengths tend to improve contrast. As an example, it would be fruitless to use 1-MeV radiation to examine a 1-mm-thick sheet of plastic, since virtually all of the radiation would pass through unattenuated, and no evidence of any internal holes would be found. On the other hand, radiation with wavelengths that are too low produce excessive scattered radiation, which reduces subject contrast. So there is an optimum range for each situation.

4.5 Sources of Radiation

4.5.1 X-Ray Sources X rays used in NDT are generated in vacuum tubes, in which electrons emitted from either hot or field-emission cathodes are formed into beams, accelerated by electric fields to energy eV_a, and caused to impact metal targets. Target materials most commonly used are tungsten or gold that is set in copper.

The interaction of the electrons with the target material generates radiation of a continuous electromagnetic spectrum, with the minimum wavelength λ_0 as given above. Some line-spectrum radiation is also possible but is unimportant in ordinary x-ray shadowgraph NDT. The continuous, or "white," spectrum has a broad peak around wavelength $1.5\lambda_0$. It is customary to refer to the x rays so produced in terms of the voltage

V_a. Thus, if the electrons on impact had maximum kinetic energy of 10^5 eV, the x rays produced would be called "100-kV x rays."

To minimize the unsharpness in the image produced by the x rays, the electron beam is generally focused so as to impact the target in a small spot. In conventional x-ray tubes, this spot size is of the order of 3 mm square. X rays are then emitted in a cone whose axis is perpendicular to the emitting surface. For specialized applications, such as producing a magnified image when the x-ray source is very close to the recording film, so-called microfocus tubes have been with fabricated, with spot sizes down to 10–20 μm.

Alternative techniques of effectively reducing the size of the x-ray emitting area or causing emission in preferred directions consist of tilting or appropriately shaping the target.

Among the equipment used to attain the required high voltages are power supplies containing voltage-doubling circuits in units operating up to 400 kV, air-core resonant transformer circuits for 1–2 MV, and Van de Graaff generators for 1–3 MV.

Vacuum tubes in which electrons are accelerated to MeV energies by dc or low-frequency fields, together with their high-voltage supplies, occupy so much space that they cannot be readily moved from one location to another. A successful alternative for generating million-volt x rays is the use of betatrons, electron cyclotrons (microtrons), or linear accelerators (linacs)—instruments that accelerate electrons to MeV energies without high electric fields external to the chamber. Such instruments can be made sufficiently compact so that they can be readily transported.

Betatrons have found considerable use in generating x rays from 2 to 31 MeV. Microtrons, though also good sources of x rays above 1 MeV, have not found great popularity. Linacs, with energy ranges from 1 to 25 MeV, are now the preferred instruments, for their x-ray output can be many times that of betatrons of the same energy (Halmshaw, 1987).

4.5.2 Gamma-Ray Sources Gamma-ray sources for NDT consist of small pellets of radioactive material that emit line-spectrum radiation of photon energies from 50 keV to several MeV, corresponding to wavelengths of 0.025 nm and shorter. The principal isotopes in use are cobalt-60, iridium-192, and ytterbium-169, with a much smaller usage also of cesium-137, thulium-170, and sodium-24. Cobalt-60, for example, emits photons of energy 1.17 and 1.33 MeV, corresponding to wavelengths of 0.00106 and 0.00093 nm. As used, a pellet is encased in shielding material, such as lead or depleted uranium, so that virtually no radiation exists external to the shielding. Mechanical systems have been devised to bring the pellet from its shielded location to the spot from which it is used to irradiate the test piece. The effective source size at this location can vary from 0.3 to 10 mm.

The advantage of using gamma rays over x-ray sources is that gamma-ray sources can be physically small, are portable, require no power or water supply, and are often less expensive. One possible disadvantage is that they could present more of a health hazard than x-ray equipment because they emit radiation continuously, whereas x-ray sources are switched to be active only during the NDT procedure. Another disadvantage in some cases is the high energy of the radiation, which, for example, causes the sensitivity of gamma-ray NDT for steel specimens less than 2.5 cm thick to be poorer than that obtainable with x rays of lower energy. Moreover, longer exposure times are required, because the radiation intensity is generally lower than achievable with x-ray apparatus.

Finally, another aspect of the use of gamma rays is the radioactive decay of the source, requiring periodic source replacement. A guide here is the half-life of the isotope used. For the three most popular materials these are for cobalt-60, 5.3 years; for iridium-192, 74.4 days; and for ytterbium-169, 31 days.

4.6 Sensing and Recording

The final steps in radiographic NDT are sensing and displaying the information in the beam that has passed through the test piece, and interpreting the results. This section deals with several methods of sensing and imaging.

4.6.1 Radiographic Film

4.6.1.1 Description. The technique of using photographic film designed for imaging spatial distributions of x rays and gamma rays remains as the most widely employed method of radiographic NDT. Since the intensities of the radiation striking the film are frequently quite weak, requiring from seconds to minutes of exposure times for x-ray sources and from a few minutes to an hour for gamma-ray sources to reach the necessary contrast in the image, means are employed to increase detection sensitivity. One of these is to use film that has a coating of photographic emulsion on *both* sides of the flexible film base.

Another technique is the use of intensifying screens. Here one distinguishes between "direct" type, also called "nonscreen" type, and "screen" type films. In the former, metallic screens, usually lead foils, are pressed on the two emulsions. Radiation absorbed in these metal screens generates free electrons, which pass into the emulsions, add to the photographic action, and thereby reduce exposure times by as much as a factor of 6. The foils used are very thin (0.02 to 0.2 mm), to prevent electrons from spreading sidewise before reaching the emulsion and increasing the image unsharpness.

An additional benefit accruing from the use of these metal screens is the reduction of "buildup," i.e., longer-wavelength radiation that arises through Compton scattering in the specimen and causes a type of fogging of the film.

Screen-type films have emulsions coated with fluorescent powders in a binder. When struck by x rays, these "salt screens" generate ultraviolet (UV) radiation. Since the emulsion is more sensitive to UV than to x rays, exposure times are reduced. However, while satisfactory for medical x-ray use, the image quality is not considered adequate for the precision needed in industrial NDT except for cases that do not require critical examinations, and for process control. The UV from these salt screens can also be used to expose photosensitive paper, to get positive prints of the x-ray pattern—again, without the great precision obtainable with film.

A successful combination of the two materials is the fluorometallic screen, which has lead layers outside of the fluorescent layers. The lead layers reduce the buildup, the fluorescent layer reduces the required exposure time from factors of 2 to 7, and the image quality exceeds that of the regular screen type of film.

4.6.1.2 Film Parameters. The following photographic parameters relate to the use of radiographic "direct" film (Halmshaw, 1987; Cartz, 1995):

1. Film density D: Films are generally exposed to a density between $D = 1.5$ and 3.5. [D relates to the viewing of the exposed and developed film with visible light and is defined as $\log_{10}$ {intensity of light incident on film/intensity of transmitted light}.]
2. The minimum density, the so-called "fog level," is usually around 0.2 to 0.3.
3. Film gradient G_D, also called "film contrast": G_D, a measure of the film's sensitivity to small changes in incident x-ray level, is the slope of the curve of D when plotted as a function of $\log_{10} E$, where E is the product of the x-ray intensity and film exposure time. It is found that G_D increases with D and that fine-grain film is more sensitive to changes in x-ray intensity than coarser-grain film.
4. Film speed: Radiographic films available from manufacturers cover a range of 20:1 in the measure of film sensitivity that is generally called "film speed."
5. Unsharpness: Among several factors that contribute to unsharpness of the image are size of radiation source and distance from test piece, thickness of intensifying screen, film unsharpness, relative motion of source and test piece, and secondary emission of electrons in the film. Surprisingly, results of experiments indicate film unsharpness to be almost independent of film graininess.
6. Resolving power: As can be expected, the greater the unsharpness, the poorer is the resolving power. A number quoted for 100-kV x rays and conventional radiographic film is 60 line pairs per mm.

4.6.1.3 Viewing the Image. A very important aspect of the conventional method of viewing the film and interpreting the image is an arrangement of good viewing conditions. This must include low ambient viewing-room illumination, no glare, and the necessary luminance. It has been found that to see small details and low contrast differences requires a minimum luminance of at least 30 cd/m^2. To see detail in areas on the film in which the density is 2.0, the luminance incident on the film is required to be at least 3000 cd/m^2.

An alternative method of film examination uses a television camera, which adds the features of permitting exploration of details in images of very low brightness, image magnification as desired, and performing computer-based image analysis.

4.6.1.4 Measurement of Radiographic Sensitivity. In industrial radiography the term "sensitivity" generally means the ability to show detail. Ever since the inception of radiographic NDT, special fixtures have been used to measure sensitivity. Originally called "penetrameters," they are now called "image quality indicators," or IQIs. Although the ability to detect a flaw in a casting or weld depends on the actual situation, the IQI sensitivity is a good measure of the size of flaw that can be detected.

Several types of IQIs are in use. A representative example is a fixture in which a series of wires of different diameters but of the same material as the specimen to be tested are strung in a frame, in essentially the same plane. To establish the sensitivity, this IQI is placed on top of the specimen, and the combination is irradiated by the x-ray or gamma-ray source of interest so that the beam passes perpendicularly through the plane of the wires. The diameter of the thinnest wire that can be discerned on the film image is a measure of the minimum size flaw that can be detected.

4.6.2 Other Sensing and Recording Media At the time of this writing, the method of recording on film has the greatest resolution over a large area. However, several other methods are also in use. Among these are the following:

1. Paper radiography—For some applications, photosensitive paper is used to record images formed by UV radiation that is emitted by salt screens struck by x rays.
2. Xeroradiography—In xerography a latent image is formed on a positively charged photoconducting plate by discharging areas of the plate to varying amounts with spatially varying x radiation that has passed through the test piece. Negatively charged pigmented particles that are brought in contact with the plate form a visible image, which can be transferred to a positively charged sheet of paper. The principal use of xeroradiography is in medical radiography.
3. Scintillating materials—Substances such as NaI(Tl), which can be fabricated in sheet form, emit light when struck by x rays. When backed by a fiber-optic plate, the structure becomes an area detector.
4. Semiconductor detector arrays—Semiconductor arrays make use of the x-ray photoconductivity of materials such as cadmium sulfide or of semiconductor junction devices. Since such components can be made microscopic in size, they can be built into line or matrix arrays of discrete x-ray detecting elements. Array-scanning circuitry develops an electrical signal by sensing changes in these elements as they are exposed to the radiation, such as changes in conductivity. This signal can be used for generating a video display, for signal processing, or for creating a "hard-copy" record.
5. Fluoroscopy—Fluorescent screens that emit visible light when struck by x rays or gamma rays present a visible image, although one that is generally of low brightness. Vacuum-tube or solid-state image intensifiers are available for improving brightness and contrast.

4.7 Real-Time Radiography

Real-time radiography, also known as radioscopy, is the technique of using results from x-ray or gamma-ray NDT procedures to create analog images for continuous viewing while these procedures are being carried out. Closely related is near-real-time radioscopy, in which the formation of images occurs after a brief time delay. One such radioscopy system is x-ray detection by the discrete components of an array, followed by array readout and the creation of an image on a television screen.

Since there is essentially real-time image formation, radioscopy techniques are applicable when there is motion involved. A well-known example is the system of luggage inspection at airports, in which a slit source of x rays shines through moving baggage toward a linear detector array. Another application is a system in which a test piece is rotated while being irradiated, to find optimum directions for finding and characterizing flaws.

The earliest system of radioscopy used a fluorescent screen, which converted incident x-ray spatial distribution to a visible-light display. A mirror placed at an angle reflected the light from the display, so that a person could see the image in the mirror without being in the path of the x-ray beam. Systems of this type are still used for examining items of low density, such as plastic or paper packets. For general inspection of metals, however, the image is too faint.

An improvement over this basic system substitutes a closed-circuit television system (CCTV) for direct viewing. Now the operator can be well removed from the test site, so that the x-ray hazard has been eliminated. Moreover, by using CCTV with image intensification, the problem of low light level has been alleviated.

An additional improvement is to use image intensification prior to image exposure to the CCTV camera. One such image intensifier is an electron tube in which the light intensity is amplified by causing electrons emitted by a layer of photocathode material adjacent to an x-ray-excitable fluoroscopic layer to form a smaller but much brighter image. A diagram illustrating such a system is seen in Fig. 5.

A real revolution in radioscopy has been image enhancement by the use of digital signal-processing techniques such as frame averaging, point brightness shifting, and spatial filtering. For example, contrast can be improved by shifting the gray scale of an image to where the human eye is most sensitive to small changes in contrast. Gray-scale steps normally too small for the eye to perceive can be stretched; others can be compressed, to preserve dynamic range. The image can be shifted to contrast and brightness ranges in which the eye is most sensitive. Fixed pattern noise can be removed. And the resolution can be improved by selectively amplifying high spatial frequencies.

A long-sought goal of radiographic NDT has been automatic inspection. So far it has been found difficult to replace an experienced human operator with a fully automatic inspection system. Nevertheless, there are expectations that new developments in expert systems and artificial intelligence will continue to make improvements toward the goal of automatic image evaluation.

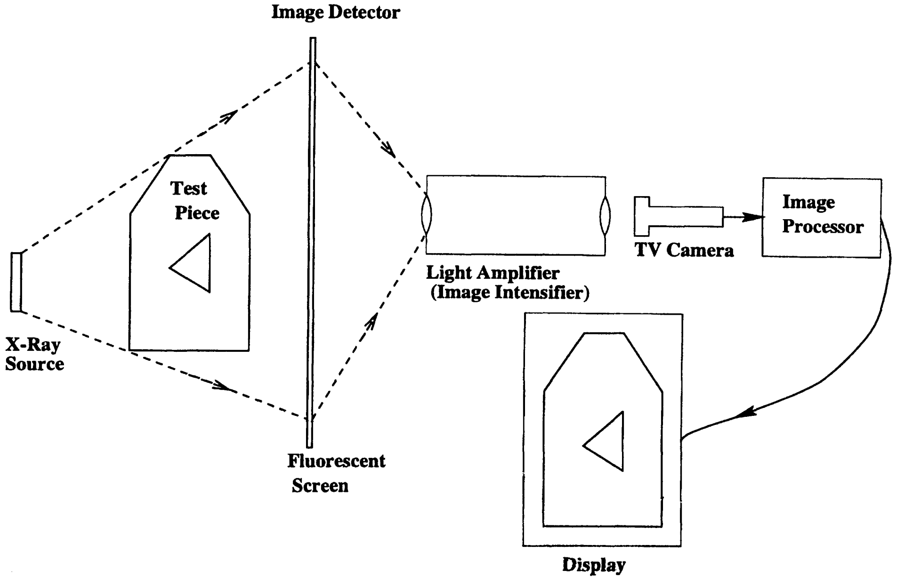

FIG. 5. Real-time radiography system.

5. ULTRASONIC NDT

Elastic waves, also called acoustic waves, can propagate in many liquids and solids over considerable distances without appreciable attentuation. Their velocity is five orders of magnitude lower than the velocity of light. These characteristics and the ease of generating, detecting, and precisely timing their progress by interaction with electrical systems have made them an important medium for carrying out noninvasive searches for imperfections in both solid and quasisolid bodies and in imaging internal structures. The latter includes living structures, such as the human body.

As shown in Sec. 5.4.3.3, to attain reasonable definition of the location of a flaw in many cases of interest, it is required that the waves used should have frequencies well above 20 kHz. Since this is above the audible, or sonic, range, the term "ultrasonic NDT" is appropriate.

5.1 Wave Types

A number of different types of waves, or modes of propagation of elastic energy, can exist in solids, each with its own velocity of propagation, particle motion, and pattern of stress and strain. Most often used in NDT are bulk waves, i.e., waves that exist without dependence on the thickness or shape of a specimen, and of wavelengths considerably shorter than specimen dimensions. Others either have actually also been used for NDT or have shown possibilities for use in special cases. Among the various modes are the following listed below. For comparison, when appropriate, the propagation velocity v of each mode in aluminum is given (McGonnagle, 1966).

5.1.1 Bulk Waves Bulk waves are of two types:

1. Longitudinal waves (LW). These are compressional/dilational waves. Particles that participate in the propagation oscillate parallel to the direction of propagation. In aluminum $v = 6.25 \times 10^3$ m/s.
2. Transverse or shear waves (TW). Particles oscillate transverse to the direction of propagation. In aluminum $v = 3.1 \times 10^3$ m/s. (The term "shear waves" is preferred in the NDT industry.)

LW can propagate in liquids as well as in solids. It is possible to generate LW in water, for transmission into a solid, *et vice versa.* TW will not propagate in liquids.

As stated briefly in Sec. 5.2.3, it is possible to convert energy from one type of wave to the other.

Both LW and TW may be used for NDT, with the choice depending on the application. For example, LW are used for measuring the thickness of a rectangular block or film; for searching for flaws in welds, TW are preferred.

5.1.2 Structure-Dependent Waves

Analysis of the possibility of acoustic-wave propagation for various structures has yielded several different wave types, or modes. The following are of interest.

5.1.2.1 Rayleigh Waves. Somewhat analogous to the propagation of water waves, Rayleigh waves are waves that propagate on smooth solids, with particle motion principally in a thin surface layer. Particle oscillations are elliptical, in the plane that is parallel to the direction of propagation and perpendicular to the surface. In aluminum $v = 2.8 \times 10^3$ m/s. Also known as surface acoustic waves, or SAW, Rayleigh waves have found uses in electronic circuits for carrying out functions of frequency filtering and high-frequency analog data processing.

A very useful feature of Rayleigh and other surface waves for NDT applications is that they can propagate on curved surfaces. Since propagation is very sensitive to surface flaws, surface waves can be used to detect surface or shallow subsurface defects, such as nicks or points of corrosion, not only on plane surfaces but also on such curved surfaces as cylinders or springs.

5.1.2.2 Love Waves. This type of surface wave can exist in a structure that is covered with a thin layer of material whose density differs from that of the substrate. Particle oscillations are in the plane parallel to the surface. Wave velocity is material and frequency dependent.

5.1.2.3 Lamb Waves. Whereas Rayleigh and Love waves propagate in a thin layer along *one* surface, Lamb-wave propagation is in thin layers that have *two* surfaces, i.e., it is propagation in thin sheets. A number of different patterns, or modes of propagation, are possible, each with a velocity that depends on the material, sheet thickness, and frequency. Anomalies in sheet thickness, such as the presence of corrosion or the presence of thin internal cavities, can be detected by measurement of wave velocity.

5.1.2.4 Stonely Waves. These are waves that propagate along the interface of two different materials. Since wave velocity is sensitive to surface conditions at the interface, the health of the bonding surface can be determined by comparative velocity measurements (Hsieh *et al.*, 1991).

5.2 Reflection, Refraction, and Mode Conversion

5.2.1 Reflection The principal ultrasonic NDT method used to find flaws in a specimen is the observation of reflections generated by these imperfections. Similarly, an ultrasonic map of a structure is based on observing and plotting the intensity and/or pulse-transit time of reflected signals. As in the treatment of electromagnetic waves, it can be said that reflections occur whenever a wave propagating in a medium of a particular "characteristic impedance Z_0" encounters a different characteristic impedance in its path. A characteristic impedance Z_0 can be defined for each mode of propagation. For LW and TW, the waves most often employed in NDT, Z_0 is defined as the product of wave velocity and material density.

For the simple case of plane waves in a medium of Z_{01} impinging perpendicularly on a boundary separating this medium from a medium of Z_{02}, the ratio of reflected energy to incident energy is $(Z_{02} - Z_{01})^2/(Z_{02} + Z_{01})^2$. More complicated expressions exist for oblique incidence.

5.2.2 Refraction Snell's well-known law of refraction for electromagnetic plane waves holds also for both longitudinal and shear acoustic waves. Thus, referring to Fig. 6, if v_1 and v_2 are the wave velocities in medium 1 and medium 2, respectively, it is found that $\sin \Theta_2 = (\sin \Theta_1)(v_2/v_1)$.

Of special interest is the case when $\sin \Theta_1$ has the value v_1/v_2, so that $\Theta_2 = 90°$. For this "critical angle" of incidence Θ_c and for angles larger than this, no waves of the original configuration are transmitted into medium 2. (However, through the phenomenon of mode conversion, waves of other configurations may be generated. Specifically, it is possible to generate a strong Rayleigh wave in medium 2 when Θ_1 is near the critical angle for shear waves.)

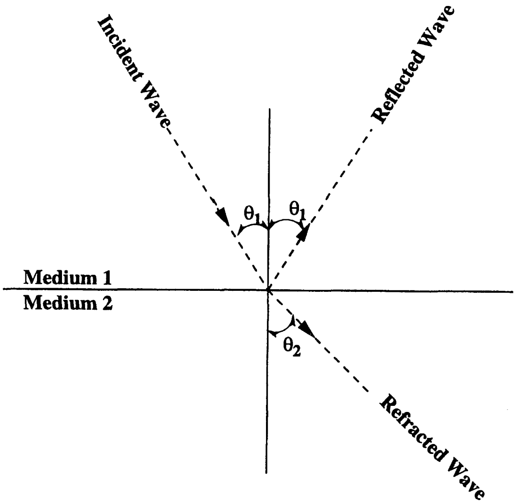

FIG. 6. Reflection and refraction of uniform plane waves at a boundary.

5.2.3 Mode Conversion In addition to the reflection and refraction that occurs at a boundary for both LW and TW, there is also a mode conversion. For when either type of wave propagates toward a boundary, reflected and refracted waves of both types exist (Knott, 1899). Since the velocity ratios of the two media generally differ for the two wave types, each of the waves propagates at its own angle. This makes it possible, for example, to generate shear waves (TW) from a source that would normally generate longitudinal waves (LW). By use of the critical-angle phenomenon, it is then possible to select only the type of wave desired and use it for NDT.

5.3 Acoustic-Wave Generation and Detection

5.3.1 Transduction—Longitudinal and Shear Waves In most cases both the generation and the detection of ultrasonic waves are carried out by the use of piezoelectric transducers that convert electrical to elastic energy, *et vice versa*. In early work these transducers were wafers of single-crystal quartz. In use for NDT now are poled ferroelectric ceramics, such as PZT (lead zirconate titanate) or PMN (lead metaniobate).

For single-crystal quartz with proper crystal orientation, when an alternating voltage is applied across the metallized plane surfaces of the wafer, it either expands and contracts axially or exhibits particle oscillations parallel to the end planes. By bonding one of the planes of the wafer to the test piece, either longitudinal or shear waves are sent into the structure. Conversely, when an elastic wave reaches the transducer from the structure, an alternating voltage appears across the two planes, so that the transducer is also a detector of elastic waves.

With a ferroelectric wafer bonded to the test piece, longitudinal waves are generated and will enter the test piece directly. If shear waves are desired, a dielectric wedge of proper angle is inserted between the transducer wafer and the test piece so that longitudinal waves cannot enter the test piece because their critical angle is exceeded, but shear waves that are generated by the mode conversion process *will* enter.

Instead of bonding the transducer firmly to the structure, it can be attached with a "couplant," such as a liquid or gel. And for the special case of longitudinal waves, the transducer can be inserted into a liquid to generate elastic waves, which can then be coupled into the solid structure. Again, coupling is reciprocal.

5.3.2 Generation of Structure-Dependent Waves Following is a brief summary of some methods used to generate various structure-dependent waves, as discussed by a number of authors. (See, for example, Krautkrämer and Krautkrämer, 1990; Lynnworth, 1989; McGonnagle, 1966; Szilard, 1982.)

1. Rayleigh waves can be generated by interdigital electrodes on a piezoelectric substrate, by transducers of proper crystal orientation (e.g., *X*-cut in single-crystal quartz), or by conical or knife-edge transducers.
2. Love waves can be launched by a shear-wave transducer.
3. Lamb waves can be launched by interdigital electrodes on a piezoelectric substrate.
4. Stonely waves have been generated by mode conversion from Rayleigh waves (Hsieh *et al.*, 1991).

5.3.3 Geometric Ultrasonic Optics The well-known techniques of geometric optics can be used to aid in ultrasonic NDT. For example, poled bowl-shaped ceramic transducers can generate converging beams. And since Snell's law holds, beams can be focused by the use of lenses with shapes similar to their optical counterparts or by electronic focusing by proper phasing of the various segments of Fresnel-zone plate structures. By using focusing structures, it is often possible to increase sensitivity when searching for small defects or when accurately sizing defects.

5.4 Methods of NDT

Three different methods of NDT have been in use: through transmission, resonance, and pulse echo.

5.4.1 Through-Transmission NDT Flaws in the path of a wave cause reflection and therefore reduce the energy transmitted onward. The transmission technique makes use of this fact by sending elastic waves of a convenient frequency through the structure under test and comparing the energy transmitted with that obtained by sending the same signal through an identical but fault-free solid. While this technique has found use in the past, it is subject to the fact that, as in an electromagnetic transmission line system, the energy transmitted depends on the thickness of the structure; so that, depending on the frequency, small deviations in thickness of thin materials can cause inaccurate results. In some early work, this problem was overcome by the use of a frequency-modulated or noise-modulated input signal (Krautkrämer and Rudiger, 1949; Schubring, 1955).

5.4.2 Resonance NDT The resonance technique makes use of the fact that a block with smooth, parallel sides is a resonator for elastic waves at frequencies at which its thickness is an integral number of acoustic half-wavelengths. When a swept-frequency sinusoidal signal is applied to a piezoelectric transducer that is fastened to one side of the block and the transducer voltage vs frequency is monitored on an oscilloscope, the reflected electrical impedance "seen" by the transducer causes peaks to appear on the oscilloscope display at the various resonant frequencies. A flaw, such as a crack that is not perpendicular to the sides of the block, can indicate its presence by weakening or destroying the resonance peaks.

5.4.3 The Pulse-Echo Technique

While the transmission and resonance methods can indicate the presence of a flaw, they do not generally indicate its location and configuration. The ultrasonic method that solves these problems is the pulse-echo technique.

In this technique a short pulse is sent from a source of elastic waves into the region to be explored. If an echo of this pulse arrives at the location of the source Δt seconds later, the imperfection that caused the echo is a distance d from the source, where $d = v(\Delta t)/2$. For example, if Δt for an aluminum specimen is found to be 100 μs, and if the wave is a longitudinal wave, for which v in aluminum is 6.2×10^3 m/s, the flaw is 0.31 m from the source.

5.4.3.1 Generation of Short Pulses. If a 1-MHz piezoelectric transducer that is completely isolated in air is excited by a delta-function voltage pulse, it will "ring" for many cycles, i.e., it will expand and contract and thereby generate a 1-MHz decaying sine-wave voltage. However, when one face is bonded to the specimen under test, while the other face is bonded to a damping mass, the transducer becomes broadband. As a result, the acoustic pulse sent into the specimen is not a "ringing" wave but a short pulse whose length in time is approximately the reciprocal of the bandwidth of the now "loaded" transducer. It is pulses generated in this manner that perform the action of the pulse-echo technique.

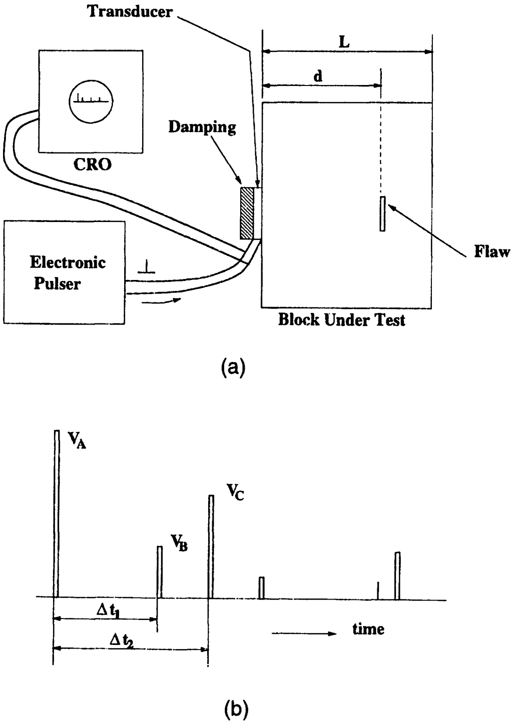

FIG. 7. Pulse-echo system. (a) Schematic. (b) Oscilloscope display.

5.4.3.2 Pulse-Echo Action. An example of the action in the pulse-echo technique is given in Fig. 7, where a transducer is fastened to the left wall of a block. As stated above, when a short voltage pulse V_A is applied to the transducer, a short acoustic pulse is sent into the block. Upon striking a flaw, a portion of the acoustic energy is reflected, thereby creating a pulse that moves back toward the transducer, which generates voltage V_B when struck by it. A second reflection, V_C, originating at the wall to the right of the flaw, is received a short time later. Additional signals, due to reflections from the left wall, the flaw, and the right wall, are also generated. These signals, which can be seen on an oscilloscope of sufficient bandwidth whose sweep is synchronized with the rate at which pulses are applied to the transducer, appear as sketched in Fig. 7(b). Here it is seen that the wave velocity v in the block shown is given by $v = 2L/\Delta t_2$, while the distance between transducer and flaw is $d = v\Delta t_1/2$.

To determine the lateral position or the extent of the flaw, the transducer can be moved along the wall, to generate displays such as Fig. 7(b) for various lateral locations.

5.4.3.3 Resolution. To find the lateral or angular location of the flaw requires that the probing wave is confined to lie in a reasonably narrow beam. Such a beam would generally be launched by a transducer of, say, diameter D, which can be considered an antenna for elastic waves and therefore follows the relation for angular beam aperture well known for electrical antennas. Specifically, the angular spread Θ in the far field for signals of wavelength λ launched by a source of diameter D is approximately $2\lambda/D$. As an example, for maximum angular spread of 0.2 radians from a source of $D = 0.01$ m, λ is found to have a maximum value of 0.001 m. For v of 6.2×10^3 m/s, this corresponds to a minimum frequency $f = v/\lambda = 6.2$ MHz. Consequently, it is the need for good resolution that is the reason for the use of frequencies of 50 kHz and higher.

The far field referred to above is the region in front of the transducer that lies at distances z larger than a distance $z_N = D^2/4\lambda$. In this region the energy density on the axis, i.e., on the center line that extends perpendicular to the transducer area, follows the inverse square law. On the other hand, in the near field, where $z < z_N$, the on-axis energy density passes through a number of maxima and minima as z increases from zero to z_N. Because of these fluctuations, it is not advisable to look for flaws in the near field of a transducer. For the values of D and λ in the example above, z_N has the value 0.025 m.

The relation of angular beam width to frequency can be seen to be readily applicable to finding imperfections in a block of material by transmission or resonance NDT. It is equally applicable to the pulse-echo technique. For by applying a short voltage pulse to a transducer designed to operate over a frequency band around, say, 1 MHz, the waves that are generated are principally those of spectral content around 1 MHz, so that the relations $\Theta = 2\lambda/D$ and $z_N = D^2/4\lambda$ still apply.

5.4.3.4 Presentation of Results. The aim of much of the development of ultrasonic NDT was to produce maps of the structure of a specimen from the data gathered by the ultrasonic test techniques. Attempts to achieve such maps included the use of chemical effects, temperature-sensitive substances, diffraction of light, orientation of microscopic particles, special phosphors, and the development of electronic tubes (McGonnagle, 1966). Ultimately, however, it has been the development of digital techniques and associated semiconductor-based devices that has resulted in ultrasonic maps of specimens. These techniques are based on digitizing and storing the data obtained by the pulse-echo method, such as that of Fig. 7, then presenting these data in map form.

It has become standard to refer to three different methods of visual presentation as A, B, and C scans, with the following meanings:

A scan: This is the display of echoes received vs time, as in Fig. 7(b). Obtained from a transducer at a specified location, it is a one-dimensional presentation that shows the existence of irregularities and their locations and relative magnitudes of echoes along a line that extends outward from the transducer into the specimen under test.

B scan: This presentation is a map of irregularities, or defects, in a cross section of the specimen. It therefore reveals the depths of such defects. An example is given in Fig. 8.

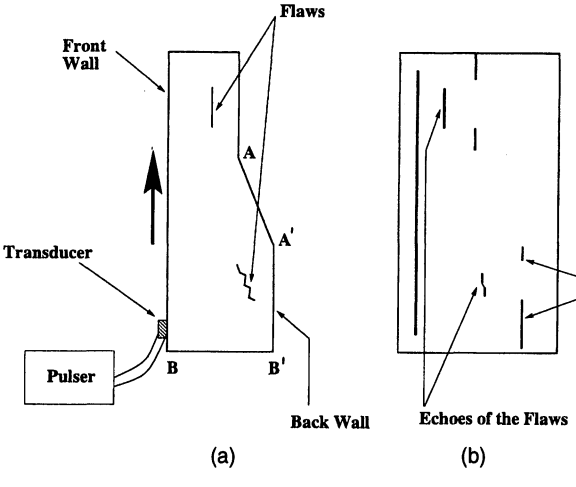

FIG. 8. B-Scan. (a) Physical arrangement. As indicated by the arrow, the transducer is moved upward along the front wall. (b) B-Scan display. For the geometry given, no echo exists for the portions of the back wall masked by the flaws. If the back wall is very smooth, the echo from portion A-A′ will be reflected to wall B-B′, where it will be reflected again, to bounce from wall to wall until it has spread or become attenuated to a level too low to be sensed by the transducer.

To produce this display, the transducer is moved along a straight line that then defines the cross section to be displayed, and time and amplitude of reflections are recorded. In a monochrome display system the intensity of the echo is indicated by the intensity of the spot or line in the display. In a multichrome display system, various colors can be used instead. An example of an actual B-scan image is seen in Plate 1.

C scan: This two-dimensional display is a map of the distribution of defects parallel to and beneath a surface of the item under test. It is generated by moving the transducer across this surface in a rasterlike manner. In any location, any echo that appears between the "transmit" pulse and the echo from the opposite side, i.e., the back wall, activates circuitry that controls the light output from a spot on a cathode-ray tube screen or a hard-copy display at the point that corresponds to the location of the transducer. The intensity of the echo determines the brightness of the spot in black-and-white display or the color in a color display. An example is seen in Plate 2.

If only defects from around a particular depth are to be shown, the display beam is turned on only around the particular time that echoes from the chosen depth are received.

5.4.4 Noncontact Coupling Although piezoelectric transducers are most commonly used in ultrasonic NDT, the requirement of mechanical contact with a test piece, either directly or through a couplant, is sometimes found to be a limitation. Examples are materials that are to be tested while at a high temperature, porous materials such as concrete that soak up liquids, and test pieces in a fast-moving production line. Noncontacting techniques for these cases can employ magnetostriction, electromagnetic coupling, electrostatic coupling, and some laser-based techniques (Birnbaum and White, 1984; Krautkrämer and Krautkrämer, 1990; Szilard, 1982).

5.4.4.1 Magnetostriction. The magnetostrictive effect in ferromagnetic materials, i.e., development of a strain upon application of a magnetic field, can be utilized by placing a small coil near a specimen and sending a high-current pulse through this coil. The result is a pulse of strain that propagates as an elastic-wave pulse within or on the surface layer of the specimen.

On the other hand, a strain in a magnetostrictive material is accompanied by a local change in permeability. Consequently, if a portion of the specimen has been placed in a region of applied magnetic-field intensity that does not change with time, the change in the permeability caused by a strain changes the magnetic-flux density, thereby generating a voltage pulse in a coil that is also in this field. The two coils therefore form a transmission/detection system of acoustic waves, similar to the system based on the use of piezoelectric transducers. Detection of flaws can be by either transmission or pulse-echo methods. Because of the high current that must be supplied to the transmitting coil, some arrangements use both a transmitting and a receiving coil. However, single-coil systems are also in use.

The magnetostrictive effect is found to increase with temperature, reaching its maximum near the Curie temperature of the ferromagnetic material. This means that for steel such a noncontacting NDT system can be used up to about 600 °C. Above this temperature the magnetostrictive effect drops rapidly to zero.

Results of tests from a particular magnetostrictive system report detection of a flaw whose area was 0.2% of the cross section of a rod, of a hole 0.8 mm in diameter and 0.5 mm deep in a 6-mm-thick plate, and of a surface scratch of depth 0.05 mm (Kaule, 1963, as reported by Szilard, 1982).

5.4.4.2 Electromagnetic Coupling. A coil carrying high-frequency currents near a metal object induces eddy currents in the surface layer of this object. If this surface layer is also immersed in a constant magnetic field, a Lorentz force $\mathbf{j} \times \mathbf{B}$ (N/m^3) exists. (Here $\mathbf{j}$ is the current density, in A/m^2; $\mathbf{B}$ is the magnetic-flux density, in T.) This force, in turn, causes elastic waves to propagate into the object. By proper orientation of the magnetic field, either longitudinal or shear waves, or both, can be generated. Moreover, the effect is reciprocal: If an acoustic wave reaches this surface layer, the particle oscillations are essentially the elements of a conductor moving in a constant magnetic field and will therefore generate voltages that cause circulating currents to flow. These will couple inductively to the external coil, which now is a detector of acoustic waves.

Using electromagnetic coupling to generate longitudinal acoustic waves of 0.6 to 1.2 MHz, a system that can detect spherical voids of 2–3 mm diameter in oblong bars at temperatures up to 1200 °C has been reported (Whittington, 1982, as reported by Szilard, 1982).

For similar pulse power and receiver gain, the sensitivity of electromagnetic systems has been reported to be about 60 dB below that of piezoelectric systems. However, by using a strong magnetic field and higher pulse power, it has been found possible to raise the received signal amplitudes and signal-to-noise ratios to levels similar to those of piezoelectric flaw-detecting systems (Szilard, 1982).

5.4.4.3 Electrostatic Coupling. If a voltage V is applied across the two plates of a parallel-plate capacitor separated by a gap of width d, an attractive force F given by $F = V^2\epsilon_0\epsilon_r A/2d$ exists. Here ϵ_r is the dielectric constant of the medium in the gap, ϵ_0 is the permittivity of free space, and A is the area of one side of one of the plates. If one of the plates is actually the side of a metallic block or the flat end of a rod, the application of a time-varying voltage will generate a time-varying force, which will generate elastic waves in the block or rod. If V varies sinusoidally in time with frequency f, the force will vary at frequency $2f$ and will have a dc component. However, by impressing a dc voltage of magnitude much larger than the time-varying voltage, the propagating wave will principally be of frequency f.

Conversely, since the voltage V across the plates is given by $V = Qd/A\epsilon_0\epsilon_r$, where Q is the charge on the positive plate, if Q is kept constant, changes in d will be reflected as changes in V. Q can be kept virtually constant by connecting the capacitor to a voltage source in series with a large resistance. Consequently, if one of the plates is the side of a metallic block or the end of a metallic rod, incident acoustic waves will generate a voltage, so that both generation and detection of acoustic waves are possible with this noncontacting scheme.

The literature describes a number of ways that this method has been used to perform NDT. While the sensitivity has been found to be about 30 dB below that of systems using piezoelectric transducers, it does have the feature of being noncontacting and broadband (10 kHz–10 MHz) (Szilard, 1982).

5.4.4.4 Laser-Generated Acoustic Waves. When a surface is heated from an external source, the energy entering the surface will spread into the body. In most cases the rise in temperature will cause the body to expand. If a short pulse of high heat is applied to a small spot on the surface and this heat cannot diffuse away rapidly enough, the expanding local volume adjacent to the heated spot will generate a stress pulse in the material and become the source of an elastic-wave pulse. As in the case of acoustic pulses generated by other means, when this pulse strikes a flaw, a portion of it is reflected. If sensed properly, the echo pulse will indicate the presence and location of the flaw.

To carry out this method of acoustic-pulse generation therefore requires a pulse that heats the surface very rapidly and with high energy density. This can be accomplished with a Q-switched laser, with beams of power density in range of 10^6 W/cm^2 or higher. Impacting a surface with such beams can generate longitudinal, transverse, and surface waves (Aindow *et al.*, 1981). Focusing and scanning of the ultrasonic energy by arrays produced by the use of multiple or scanned optical beams has also been demonstrated (Addison *et al.*, 1987). To prevent damage to the surface, it can be covered with a membrane, with a thin layer of liquid interposed.

To be a useful system, the transducer receiving the echo pulse must also be noncontacting. This can be accomplished by using reflections of the light of an auxiliary low-power laser from the surface of the test piece in an arrangement using optical interferometric techniques (Monchalin and Heon, 1986).

The cost of such an NDT system is considerably above that of methods described earlier. However, since it is based on the use of optical beams, it has the advantage of permitting nondestructive testing of a specimen from distances of several meters.

6. EDDY-CURRENT TESTING

The term "eddy currents" is used to refer to circulating flows of fluids and to circulating electric currents in conductors. The latter exist whenever time-varying magnetic fields penetrate surfaces of electrical conductors. In most situations efforts are made to minimize these electric eddy currents because they result in energy losses. However, they have found extensive use in the nondestructive testing of metallic components and structures. Applications include the detection of cracks, voids, and inclusions; sorting of components in accordance with their electric or magnetic properties; measurement of the thickness of metallic plates, tube walls, and coatings; precise dimensional measurements of symmetric parts such as ball bearings; and the detection and location of hidden metal objects.

An advantage of eddy-current testing over some other methods is that no physical contact is required. It can therefore be readily used to carry out automatic inspection of newly fabricated metallic tubing and other parts. As a result, the total number of NDT procedures using eddy-current inspection probably exceeds all other types.

A number of individuals have contributed to the development of the technique. The most prominent of these, Dr. Friedrich Foerster, who carried out this work in the period 1950 to 1965, has been cited as "the father of modern eddy current testing" (McIntire and McMaster, 1986).

6.1 Frequency-Domain (Sinusoidal) Eddy-Current Testing

6.1.1 Principle of Operation Eddy currents can be generated in electrically conducting materials by the flow of time-varying desired electric currents because

1. in accordance with Ampère's law, an electric current is always accompanied by a magnetic flux Φ adjacent to or surrounding it;
2. by Faraday's law, $V = -d\Phi/dt$, this time-varying flux causes a voltage V to exist around any closed path through which the flux passes.

Consider the arrangement of Fig. 9, in which a coil of wire is connected to a source that causes a sinusoidally time-varying current to flow through it. This current is accompanied by a sinusoidally time-varying magnetic flux that passes axially through the coil. If a loop of wire is located below the coil, as shown, some of the magnetic flux passes through this loop and generates a sinusoidally time-varying voltage. With the loop open-circuited, this voltage appears across the ends. If the two ends of the loop are connected to each other, on the other hand, a sinusoidally varying current flows in the loop, of magnitude and phase determined by its resistance and inductance and the frequency of the sinusoid. This current, in turn, generates magnetic flux that alters the net magnetic flux in the loop and in the coil. Sensing the amplitude and phase of the net magnetic flux passing through the coil, or of a quantity related to this flux, such as the coil voltage, provides an indication of the current flowing in the loop and thereby of its resistance and inductance.

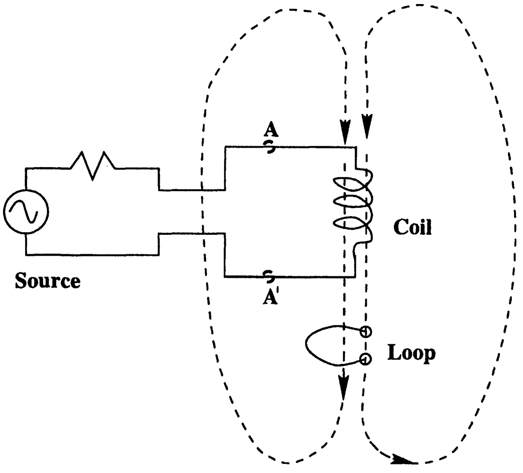

FIG. 9. Sinusoidally varying current in coil generates voltage across the ends of the loop.

An indirect method of sensing is the measurement of the input impedance Z_{in} seen when "looking" into the coil. This is because the coil/loop system can be represented by the simple equivalent circuit for a magnetically coupled linear system of Fig. 10, where R_1 and R_2, and L_1 and L_2, are the resistances and self-inductances of coil and loop, respectively. M, the "mutual inductance," is determined by the fraction of magnetic flux generated by the coil that also passes through the loop.

Using standard phasor analysis, in which all currents and voltages are assumed to vary as exp $(j\omega t)$, where $j = \sqrt{-1}$ and ω is the an-

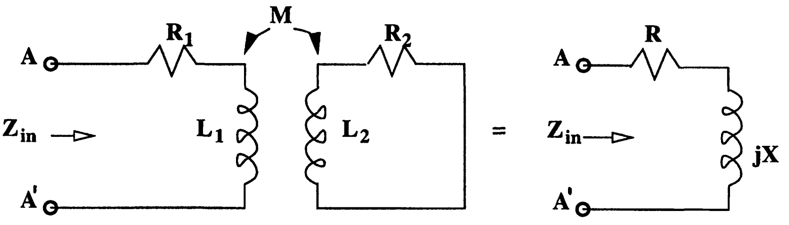

FIG. 10. Equivalent circuit of magnetically coupled coil–loop system.

gular frequency of these quantities, the complex input impedance Z_{in} at this frequency is found to be

$$\begin{aligned} Z_{\text{in}} &= R_1 + j\omega L_1 + \omega^2 M^2/(R_2 + j\omega L_2) \\ &= [R_1 + \omega^2 M^2 R_2/(R_2^2 + \omega^2 L_2^2)] \\ &\quad + j\omega[L_1 - \omega^2 M^2 L_2/(R_2^2 + \omega^2 L_2^2)] \\ &\equiv R + jX. \end{aligned} \tag{1}$$

As seen, both the real part R and imaginary part X of Z_{in} or, expressed alternatively, both magnitude and phase of Z_{in}, depend on R_2, L_2, and the magnetic coupling, expressed by mutual inductance M.

Since M depends on the separation between coil and loop, in eddy-current NDT it is often referred to as "lift-off."

Plots of the locus of Z_{in} vs R_2 in the complex impedance plane for three different values of M and continuously varying values of R_2 are given in Fig. 11. The top point of this figure for each curve corresponds to the case of infinite resistance of the loop, i.e., to the open loop. The bottom point for each curve is the loop of zero resistance, i.e., $R_2 = 0$. For $M = \sqrt{L_1 L_2}$, all of the magnetic flux of the coil passes through the loop.

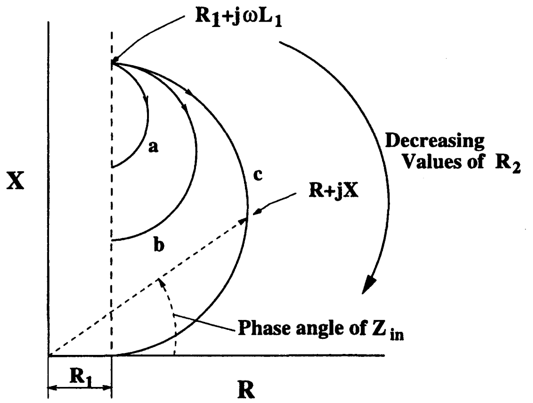

FIG. 11. Plot of Z_{in} vs R_2 in complex plane for three different values of the fraction of magnetic flux that passes through both coil and loop, represented by mutual inductance M: (a) $M \ll (L_1 L_2)^{1/2}$; (b) intermediate value of M; (c) $M = (L_1 L_2)^{1/2}$.

The measurement of R and X or of the magnitude and angle of this complex quantity, or of deviations of R and X from the corresponding values of a "standard," are the bases of sinusoidal eddy-current testing. In this NDT procedure the "loop" referred to above is actually an equivalent volume of a ring of metal through which magnetic flux will pass when a coil is placed adjacent to it and connected to a sinusoidal voltage source of angular frequency ω. Examples are seen in Fig. 12.

In Fig. 12(a) a small test coil, generally called "probe coil," is placed above a metallic block and connected to a sinusoidally varying voltage source. The current flowing in this coil generates a sinusoidally varying magnetic flux that passes into the block and induces eddy currents in the block in an "equivalent loop." The input impedance Z_{in} seen when looking into the test coil depends on the dimensions and conductivity of the volume and material of this "equivalent loop."

We now consider what will happen to Z_{in} when an operator moves the probe coil parallel to the surface of the block, with constant spacing above the surface. If the block is of uniform conductivity and there are no internal discontinuities, both the real and imaginary components of Z_{in} will remain the same, except when the probe coil is near an edge. Should the coil be passed over sections of the block of varying conductivity, however, the resistance of the "effective loop" will change, therefore changing both resistive and reactive components of Z_{in}. Similarly, if the test coil is passed over a section

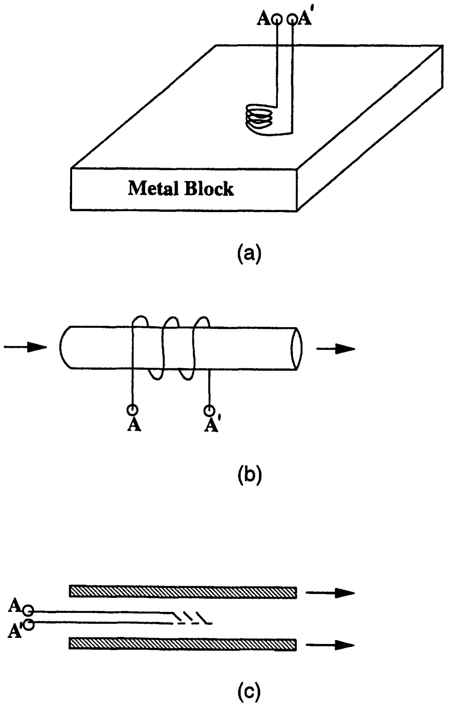

FIG. 12. Methods of carrying out eddy-current NDT: (a) Probe coil adjacent to a metal block. (b) Coil surrounding rod or tube. (c) Coil inside a metal tube.

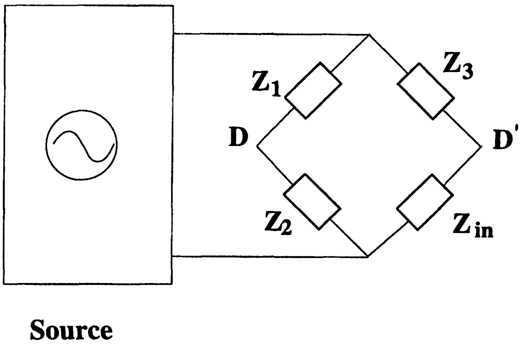

FIG. 13. Basic circuit for measurement of Z_{in} of probe coil.

of the block that contains a crack lying transverse to the direction in which eddy currents would normally flow, the effective path length for eddy currents is increased, again changing the value of Z_{in}. Continuous monitoring of Z_{in} will therefore alert the operator to a change in the material below the test coil.

The same considerations apply to the structure of Fig. 12(b), where a metal rod is moved through a test coil. Changes in the conductivity of the rod, the presence of cracks that impede the flow of circumferential currents, or changes in the shape or diameter will all be reflected into changes in Z_{in}.

A basic circuit that can be used to identify these changes is a bridge circuit, as that of Fig. 13, where the values of Z_1, Z_2, and Z_3 have been chosen so that the bridge is balanced and voltage $V_{DD'}$ is zero when Z_{in} has what can be considered the design center, or standard, value. The amplitude and phase of unbalance voltage $V_{DD'}$ can be used to identify the type of deviation, i.e., is it a change in conductivity or a change in diameter. Modern test apparatus essentially performs this basic function, but with added processing capabilities and such enhancements as memory, display of results, and, possibly, automated inspection of products flowing from a production line.

Another method of sensing changes is by the use of another, or secondary, coil, through which some of the magnetic flux is allowed to pass. For a thin sheet this secondary coil can be below the sheet. In both cases the desired information about the specimen can be extracted by measurement of amplitude and phase of the open-circuit voltage of this secondary coil.

A third method of sensing is by the use of one or more semiconductor probes, which measure the magnetic field by use of the Hall effect.

6.1.2 Depth of Penetration An important point in these measurements relates to the volume effectively probed by the magnetic field. The two aspects that determine this volume are a geometric factor and the skin effect.

6.1.2.1 Geometric Factor. One aspect of the geometric factor is evident in Fig. 12(a), from which it is rather obvious to see that for close spacing of coil and block the magnetic field from the test coil has appreciable magnitude principally in the area whose diameter is not much larger than the coil diameter. If the coil is some distance above the block, the lift-off effect spreads the area but reduces the intensity of the magnetic field within the block. This lift-off effect can be used to monitor the separation between test coil and block. For the case of a nonconducting layer on a metal block, it can therefore be used to measure the thickness of this layer.

A geometric effect is also found in Fig. 12(b), where induced currents flowing at the smaller radii of a rod under test are found to contribute less to influencing the input impedance or the voltage of a secondary coil than induced currents at the larger radii. This effect, which is relatively frequency independent, has been called the "coil shape effect" (Libby, 1971).

6.1.2.2 Skin Effect. The skin effect is a well-known effect that limits the penetration of electromagnetic fields into a good conductor. Specifically, if a uniform tangential electric field of form $E_0 e^{j\omega t}$ exists at surface $y = 0$ of a material that extends from $y = 0$ upward toward infinity, the electric field at any value of $y > 0$ is $E_0 e^{-y/\delta} e^{-jy/\delta} e^{j\omega t}$. Here, in SI units, $\delta = (2/\omega\sigma\mu_0\mu_r)^{0.5}$, where σ is the conductivity, $\mu_0 = 4\pi \times 10^{-7}$ H/m, and μ_r is the relative permeability. The quantity δ is generally called the "skin depth."

As an example, for copper at 1000 Hz, with $\sigma = 5.80 \times 10^7\ (\Omega\text{-m})^{-1}$, δ is found to be 2.1 mm. Consequently, if Z_{in} were measured at 1000 Hz while the test coil is moved along the surface of a copper block, flaws or changes in conductivity in the block at depths greater than a few millimeters would not change Z_{in} or the open-circuit voltage of a secondary coil significantly. Similarly, flaws that lie within the material of Fig. 12(b) a few skin depths below the cylindrical surface will not affect the value of Z_{in} and would therefore not be detected.

The dependence of depth of penetration on frequency allows tests to be performed that delineate changes in conductivity or the presence of flaws as a function of depth into a material. Thus, for example, a test frequency of 64 kHz will generally measure relative conductivity in nonmagnetic metal strips or slabs of thickness 3 mm or greater. To determine the presence of flaws or changes in conductivity for depths greater than 3 mm requires testing with lower frequencies. In practice, the test frequencies of commercial units vary from 5 Hz to 10 MHz.

The testing of conducting ferromagnetic materials of high relative permeability requires special consideration, since the skin depth varies as $\mu_r^{-0.5}$. For these materials, frequencies in the high kilohertz region restrict eddy currents to exist in a very shallow layer near the surface. This permits the detection of seams and laps or service fatigue cracks. If deeper penetration is desired, frequencies as low as 5 Hz can be used.

An alternative method for testing magnetically active conductors, such as steel, is to apply a strong dc magnetic field that saturates the material magnetically, thereby reducing the relative permeability μ_r close to unity for small ac signals.

6.1.3 The Importance of Phase This section discusses the changes in Z_{in} that are sensed as a test coil is scanned along a bar or cylinder that has deviations from a "standard" because of one or more of several properties. The differences in the changes are seen by looking at changes in Z_{in} due to lift-off and to changes in conductivity for Z_{in} of a test coil that surrounds a cylindrical nonmagnetic rod.

A number of individuals have performed calculations of the input impedance Z_{in} for a test coil for such a system. In applying these results to NDT, the results are often normalized by first subtracting the coil resistance, then dividing the values of reactance and resistance by the reactance of the empty coil, to arrive at a quantity $Z'_{\text{in}} = R' + jX'$. The general shape of the locus of Z'_{in} as the conductivity of the rod varies from zero to infinity is given by the curves of Fig. 14 (Libby, 1971). Curve (a) is for a tight-fitting coil. For curve (b) the rod diameter is smaller than that of the coil. As in the case of the loop, an increase in conductivity corresponds to clockwise progression along the curves. Points P, Q, and T relate to changes in the phase angle of Z'_{in}, i.e., $\tan^{-1}(X'/R')$, as a long rod is passed through the test coil.

Let us now assume that Z'_{in} for the section of rod of a certain conductivity σ_0 with tight-fitting test coil is given by the directed line O-P. If the next section of rod has the same diameter but has lower conductivity or contains a flaw, the change in Z'_{in} is given by directed line P-Q. If, on the other hand, the conductivity is the same but the diameter of the rod has decreased, the change in Z'_{in} is given by directed line P-T. Consequently, by monitoring the change in phase of Z'_{in}, it is possible to tell whether the change in Z'_{in} is

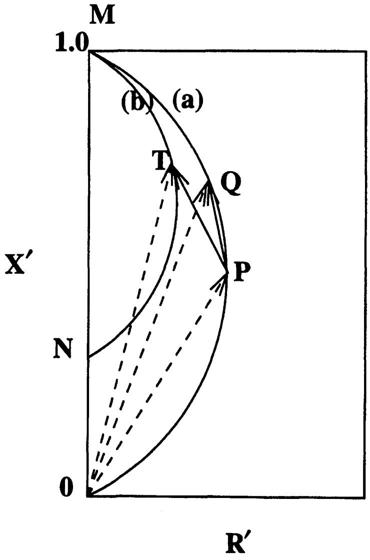

FIG. 14. General shape of locus of normalized complex impedance Z'_{in} for test coil surrounding a metal nonmagnetic rod, as conductivity of rod varies from zero (point M) to infinity (points O and N). Curve (a) is for a tight-fitting coil. For curve (b) the rod diameter is much smaller than the coil diameter. For the significance of points P, Q, and T, please see the text.

due to a change in separation of test coil from specimen, i.e., lift-off, or the presence of a flaw or change in conductivity.

While the above has dealt with the case of a rod within a coil, the same principles apply also to other geometries.

6.1.4 Instruments Over the years, the development of sinusoidal eddy-current NDT has reached a high level of sophistication. For example, an eddy-current probe in use since 1970, which is composed of two orthogonal windings, virtually ignores variations in material conductivity, lift-off, and permeability, to concentrate strictly on flaw detection. This probe is reported to detect surface flaws in magnetic materials that are only 0.13 mm deep (Kenton, 1970).

Instruments commercially available now combine the phase analysis discussed above with memory, computer, and display techniques. Examples of the results of the use of such an instrument are seen in Fig. 15. This figure is an oscilloscope display of the stored output as a probing coil is scanned along the surface of a metal plate for two cases. The nearly horizontal line shows the output as the probe that virtually ignores changes in lift-off is scanned along a metal strip at different spacings. Superimposed on this is another scan that was obtained as the same probe was scanned over a region that contained a flaw.

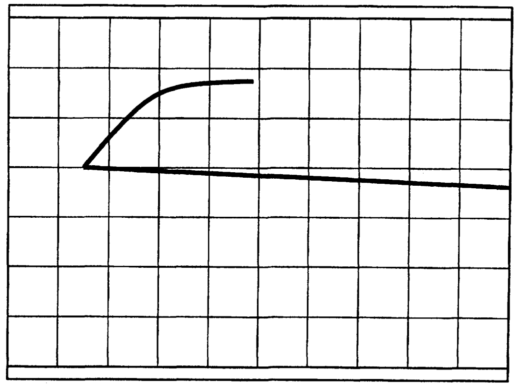

FIG. 15. Oscilloscope display from an instrument used to carry out sinusoidal eddy-current NDT. (Courtesy of Centurion NDT, Inc., Schaumburg, IL.)

6.1.5 Multiple-Frequency Testing Although most sinusoidal eddy-current measurements are conducted at a single frequency, in some cases several frequencies can be used. Specifically, conductivity could be measured by use of a high-frequency source, with only shallow penetration, while a low-frequency source would search for flaws at greater depths within the material. In another test, results with one frequency could determine the lift-off spacing, while another frequency would probe the specimen. The possibility of simultaneous monitoring with several frequencies to determine several parameters, such as the thicknesses of layers of different metals in a sandwich type of structure, or to separate interfering signals from portions of a structure that would mask desired signals, has also been considered.

The use of a number of frequencies for NDT of the multilayer structure is based on the fact that such a structure, for nonmagnetic materials, can be represented by a linear electric ladder circuit. For such a circuit the input impedance is a unique function of frequency. Consequently, by performing measurements of amplitude and phase at several frequencies and inserting the measured data into a set of simultaneous linearly independent algebraic equations, the desired parameters can be extracted (Libby, 1971).

6.2 Time-Domain (Pulsed) Eddy-Current Testing

While the sinusoidal method is the commonly accepted technique of eddy-current testing, there are cases in which time-domain methods have been found more appropriate. Examples are a noncontacting technique of determining the resistivity of a metal specimen, the measurement of the thicknesses of layers in a multilayer metal structure, and the search for irregularities in the fuel/cladding interface of nuclear fuel elements. These techniques are based on the fact that for good conductors such as metals, for which displacement currents are negligible when compared to Ohmic currents, the equation that governs the behavior of magnetic-flux density **B**, expressed in SI rationalized units, is

$$\frac{\partial \mathbf{B}}{\partial t} = \frac{\rho}{\mu_r \mu_0} \nabla^2 \mathbf{B}, \qquad (2)$$

where ρ is the resistivity, μ_r the relative permeability, and $\mu_0 = 4\pi \times 10^{-7}$ H/m. Solutions to this equation reveal that magnetic-flux density propagates in a good conductor by a diffusionlike process, with the velocity of propagation proportional to $t^{-0.5}$, where t is the time since the initiation of a nonequilibrium situation. Since magnetic-flux density and currents are intimately tied together, a similar result of diffusionlike propagation is obtained for the transient behavior of electric current in a good conductor.

For metal structures with thicknesses of a fraction of a millimeter to several millimeters, the effective propagation times are from a few microseconds to milliseconds. Transient events of such duration are readily observed in the laboratory.

The following sections describe some methods involving eddy currents that utilize the behavior that is governed by the above equation.

6.2.1 Measurement of Resistivity In this procedure, a cylinder of the material whose resistivity is to be measured is surrounded locally with a small "pickup" coil and then inserted into a larger "magnetizing" solenoid. A step function of current is sent through this solenoid, to produce a suddenly applied magnetic-field intensity H_0. The resulting time-varying magnetic-flux density generates a voltage in the pickup coil that eventually decays exponentially as $\exp(-t/T_R)$, where $T_R = K/\rho$, and K is a calculable constant determined by the cross-sectional dimensions of the cylinder. Resistivity ρ is found from the value of T_R extracted from the exponential decay curve (Bean *et al.*, 1959).

In a preferred method of carrying out this test, a steady magnetic field is established in the solenoid by the applied current, which is then suddenly interrupted. Although the polarity of the coil voltage is now reversed, the rate of the exponential decay remains the same.

Since the pickup coil is mainly sensitive to the material it encloses, average local resistivity may be measured by moving the pickup coil along the axis of the cylinder.

6.2.2 Pulsed Eddy-Current NDT The development of pulsed eddy-current NDT in the United States received its start in the 1950s (Waidelich, 1956). The objective of this initial work was to determine the thickness of a layer of a metal A that was cladding to a thick plate of a metal B. Magnetic-field pulses were sent into this cladding through the application of current pulses of high intensity to a small single-layer coil that was adjacent to the cladding and had its axis perpendicular to the plane of the cladding.

Had this coil been far removed from the metal, the application of a step function of current would have produced a high spike of coil voltage. Instead, the magnetic field produced by the coil current and coupled into the metal caused eddy currents to be generated in the layer of metal adjacent to the coil, thereby replacing the spike with a more gently rising voltage.

Now, with a ring of current density and its magnetic field in the top layer of the conductor, this current density and associated magnetic field would follow the diffusionlike action predicted by Eq. (2) and move toward the base metal, reaching it after time interval $t = d^2\mu\sigma$, where μ is the permeability, σ is the conductivity, and d is the thickness of the cladding.

Since the base metal had a different conductivity than the cladding, a reflection occurred, sending the current density and associated magnetic field back toward the front surface. The result was a voltage pulse across the coil that rose rather steeply, then decayed gradually and became negative, having passed through zero at time T given by $T = 2d^2\mu\sigma$.

While in the above discussion a step function of current and therefore of magnetic-field intensity H was assumed, Waidelich demonstrated that pulses of less abrupt rises could also be employed.

As demonstrated in this work, the basic idea of this method of eddy-current testing is that the duration of the "output" pulse voltage seen across the exciting coil is altered by changes of the conductivity or permeability encountered by the diffusing current and magnetic-flux densities. These changes could be due to actual changes in the metal, as in the change from cladding to base metal, or the presence of a crack or other irregularity.

When another coil is placed on the opposite side of a metal sheet, it is found that the signal transmitted through the sheet is attenuated by amounts that depend on the thickness of the sheet and the pulse length. In general, the thicker the sheet and the shorter the pulse, the higher the attenuation. Researchers have made use of these facts in efforts aimed at improving the spatial resolution while scanning an area over that attainable by an open exciting coil by enclosing this coil in a metal box that has a small aperture. Since virtually no magnetic flux passes through the metal walls of the box, the area probed is limited to the area of the aperture.

In another improvement a separate sensing coil is added and placed so that there is no direct coupling from the aperture to this sensing coil but that fields emanating from the metal are sensed. For other applications this sensing coil is placed on the other side of a sheet of metal that is to be scanned, so that anomalies in the transmission over that from a "standard" can be detected.

In adapting pulsed eddy-current testing to systems in which component parts move past an inspection station, systems have been developed that make use of the fact that the time that an anomaly in the "output" signal is observed depends on the depth of the defect in the metal. By electronically sampling the output signal at several distinct points of time and comparing these sampled signal intensities with those from a "standard," an alarm signal alerts the operator that an anomaly exists. By noting the point of time of sampling corresponding to the alarm, the approximate location of the anomaly is found.

7. ACOUSTIC EMISSION TESTING (AET)

7.1 AET—An Active Type of NDT

7.1.1 Acoustic Emission The use of acoustic emission, AE, also called stress-wave emission, stress-wave microseism, microseismic activity, and rock noise, as a method of nondestructive testing is essentially an adaptation to components and structures of the techniques of detecting, source locating, measuring the intensity, and assaying the damage associated with earthquakes. It is based on the observation that the rapid release of localized stored elastic energy during irreversible structure changes in materials subjected to mechanical stress generates transient acoustic waves that propagate through the material. Such release of potential energy occurs during the formation or extension of a crack or by the motions associated with dislocations, slip, twinning, grain-boundary sliding, and fracture and decohesion of inclusions. Composites are also found to emit such transient waves during debonding, cracking, and the fracture of fibers.

Since AET causes permanent modifications, one might argue that it should not be considered a method of nondestructive testing. Nevertheless, it has been accepted as one of the standard NDT techniques.

7.1.2 Development of AET Although there are some earlier reports of the emission of sonic or ultrasonic noise from materials under stress, AET had its origin in the pioneering work of Josef Kaiser, carried out shortly after World War II. In his first journal article on the subject (Kaiser, 1953) he discussed applying tensile stresses to various metals and detecting sonic or ultrasonic pulses as these stresses were applied in increasing amounts. He recognized that the detection of these pulses could be a big step forward in materials testing, which heretofore had been performed by destructive methods. His work sparked further research, thereby resulting in the foundation of AET (Schofield *et al.*, 1958).

7.1.3 AET and Other NDT Techniques By sensing changes that occur while a component or structure is loaded, AET has become a method of monitoring structural integrity, characterizing material behavior, and discovering the beginning of failures in components or structures. It is ultimately a method aimed at arriving at allowable safe limits of operation. In addition it can be used to find regions in a structure that exhibit weaknesses, so that these regions can be examined in more detail by other NDT techniques.

The equipment used to detect acoustic emission will also detect transient acoustic waves that arise from other sources, such as from friction associated with moving parts or from leaks or cavitation. The differing characteristics of signals from these various sources, as well as the extensive use of computers in the analysis of AET, has made it possible in many cases to distinguish between signals from stress-caused emissions from those of these *secondary* or *pseudo* sources.

Most other NDT methods are static methods. Their mission is to find and characterize irregularities or flaws that already exist at the initiation of a testing procedure, without creating any changes in the test piece. AET, a dynamic method, can locate some flaws already in existence, but its principal use is to detect changes in the test piece as it is stressed, with the aim of finding limits to the stresses that can be safely imposed. Often some of these changes occur because of flaws already in existence, such as in the enlargement of a crack.

AET also differs from other types of NDT in the method of finding flaws. In other NDT procedures a detailed search for flaws is carried out by observing the signals that are the response as a volume is scanned in some manner with a small amount of *injected* energy. In AET no scanning is necessary. Since the observed signals are elastic wave pulses created totally within the test piece, these sources can, in principle, be found by triangulation, based on the different times of signal arrival at several conveniently placed stationary transducers.

AET is frequently carried out by gradually increasing the applied stress up to some maximum, or "proof," value. If the results are satisfactory for repeated stresses up to this proof value, the unit under test is expected to function well in actual operation.

AET may also be carried out over long periods of time by the monitoring of elastic-wave signals that are generated while the unit is in service. Such continuous monitoring can reveal the formation and enlargement of fatigue or corrosion cracks and their effects on lifetime without interrupting the operation of the unit—a procedure not generally feasible with other methods of NDT.

An additional significant difference between AET and some other NDT methods is that a major aim of the latter generally is to find geometric data relating to irregularities, such as location, size, shape, and orientation. While spatial information is also an important part of the data obtained from AET, an even more important aspect is time. Specifically, what is detected by AET sensors is a large number of pulses of variable shape, amplitude, and time duration.

7.1.4 Signals Detected Two types of signals are detected. Continuous emission is characterized by emission "events" of comparable amplitude in which the average time interval between the beginning of consecutive emission events is less than or comparable to the duration of each of these events. This is the case of signals that are found to occur in the plastic deformation during and after yield of a material, when many low-level pulses interfere and result in an output signal that has the appearance of white noise. Such signals have been used in the study of the microstructure of materials. (Heiple and Carpenter, 1987). Of greater interest for practical AET is emission in individual bursts, associated with the formation or enlargement of cracks. To evaluate the effect of such burst emission requires rapid sensing, storing, and processing of a large amount of data. As a result, computer tie-in has become an essential part of AET.

7.1.5 The Kaiser Effect During Kaiser's exploratory work he discovered that when his specimens were stressed in increasing steps, he was able to detect AE. But when the stress was removed and then reapplied, no emission occurred until the maximum stress that had been applied earlier was exceeded. This behavior, which is now known as the Kaiser effect, was later found to exist only in certain materials and gave rise to additional research.

In what is now known as the Dunegan corollary (Dunegan *et al.*, 1970), it is now believed that for some materials emission below the previously maximum load indicates that the material had incurred some damage because the presence of a crack would increase the local stress for the same applied load.

7.2 Measurement Techniques

7.2.1 Basic Measurement Technique Measurement systems for AET consist of acoustic transducers followed by high-gain amplifiers, frequency filters, amplitude discriminators, counters, and computers to interpret the data and display results. The transducers generally are piezoelectric wafers of a thickness chosen to cause the transducer to be resonant at a specified frequency. They are attached to the test piece with an acoustic couplant, such as a thin layer of grease. If the structure to be tested is in an environment in which the transducer can become nonfunctioning, such as at high temperatures, an acoustic waveguide can be used to isolate the transducer from the structure. Such a waveguide can be a rod up to several meters in length that has one end firmly attached to the specimen under test and the transducer mounted on the opposite end.

Acoustic-emission signals can have appreciable spectral content from low audio frequencies to the megahertz range. The range from 100 to 300 kHz has been found to be optimum for detection. This avoids low-frequency noise from nearby machinery as well as high-frequency signals that could be misleading because of acoustic attenuation at high frequencies.

7.2.2 Continuous Emission Continuous emission signals, mentioned above, have the appearance of white noise. The signals emitted by the pseudo sources of leaks in a pressure vessel and cavitation also fall in this category. Because of the continuous nature of this type of emission, an accepted standard method of quantifying the amount of continuous emission is the rms value of the output voltage of a standardized transducer.

7.2.3 Burst Emission The two items of interest for burst emission are to find the locations of emission sources and to obtain data that will permit an assessment of the degree of integrity of the structure under test.

As stated above, in principle the location of a source can be found by the use of differences in arrival time of the same signal at several transducers. For example, for a source in a plane the use of three transducers permits the source of emission to be found at the intersection of hyperbolas whose equations contain coordinates of these transducers, the acoustic-wave velocity, and the differences in arrival time of a pulse at these transducers. While for arbitrary shapes the situation is not as straightforward, the locations of sources of burst emission can be generally found by judicious placement of several transducers.

7.2.4 Interpretation of Data Most important in the use of AET is the interpretation of experimental data. Here several quantities that provide a good measure of predictability have evolved. The first and oldest of these is the "number of counts," also called "ringdown count" or simply the "count," which is derived from the output voltage of a resonant transducer that monitors burst emission. Because transducers are chosen to be resonant systems, the voltage output for an event, i.e., when it is struck by a burst emission pulse, is a wave train, somewhat as in Fig. 16(a). To convert this into a signal that provides information about the condition of the test piece, the amplitude of this time-varying voltage wave is compared to a "threshold" voltage. Whenever the peak of any cycle of this wave exceeds this threshold voltage, the system generates a digital pulse, as seen in Figs. 16(b) and 16(c). The number of counts for this emission sig-

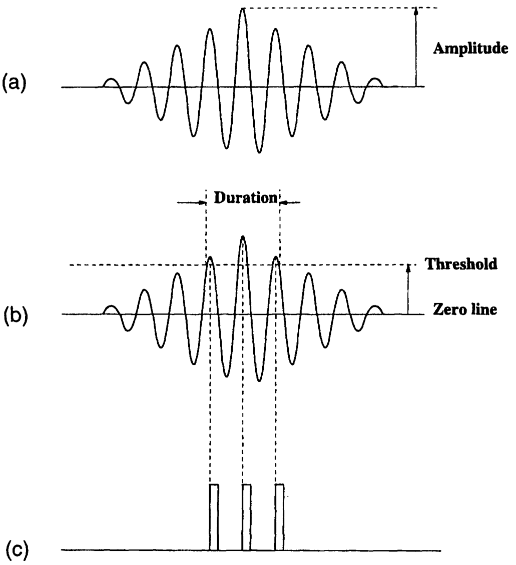

FIG. 16. Formation of counts: (a) Representative output voltage when resonant transducer is struck by an acoustic-emission pulse. (b) Threshold voltage used to formulate the "count." Also shown is the "duration." (c) Digital pulses formed by circuitry, as based on positive peak exceeding the threshold voltage. In this example the count is three.

nal is the number of pulses generated in this manner.

Since the number of counts depends on the arbitrarily set threshold voltage as well as on the acoustic properties of the item under test, the use of this number is clearly very subjective. Nevertheless, it has been found to be a satisfactory way of determining the integrity of structures under test. One way of using it is to plot the total number of counts accumulated, which is generally in the thousands, as a function of applied load while the load is gradually increased in steps. Experience has shown that as the load on a structure is increased in this manner, the count also increases. If the increase of the count is gradual with increase in the loading, up to and above (by a safety factor) the loading used during operation, the structure can be considered sound. On the other hand, if the count shows a steep increase during the test, it is quite probable that a microscopic crack that has been formed is increasing in size, thereby increasing the strain at its ends and eventually causing the crack to become large enough to cause the structure to fail.

A plot of accumulated counts as a function of load (or time, for a load that increases with time) is only one type of display that depicts the behavior of a structure. Among other displays in use are a histogram whose shape is essentially the derivative of the plot of accumulated counts, or similar plots in which the number of counts of an event is replaced by "energy counts." The latter is a number proportional to the area above the horizontal centerline of a wave train such as that of Fig. 16(a). This quantity, also known as MARSE, the acronym of "measured area under the rectified signal envelope," is sensitive to both amplitude and wave-train duration. Since there is no threshold level and MARSE is less frequency dependent, it is now preferred over the use of counts (Pollock, 1989).

Among other quantities used in the interpretation of AET data are duration and amplitude relating to an event. For example, duration, defined as the time interval between first and last threshold crossing, has been used to recognize special long-duration deleterious processes, such as delamination in composite materials.

The amplitude of an AE event, defined as the highest voltage reached by a transducer output signal for an event, is found to vary in the same test from tens of microvolts to volts. Because of this wide range, some AET instrumentation systems use logarithmic amplifiers.

A cumulative amplitude distribution displays the number of events whose amplitudes exceed voltages $A_1, A_2, \ldots, A_n$ as the load on a specimen is increased in steps. A simplified example illustrating this amplitude distribution is given in Fig. 17.

As they appear during a test, displays of the type of Fig. 17 present a virtually real-time view of the progress of the AE test. It has been found that for some metals the appearance of the beginning of large amplitudes is a sign of the enlargement of cracks. Similarly, the appearance of large-amplitude signals during progressive loading of fiberglass has revealed and will tell the observer the stress levels at which fiber breakage is initiated (Pollock, 1981).

In summary, thanks to the use of computers that are an integral part of the complete AE test setup, much AET information is now

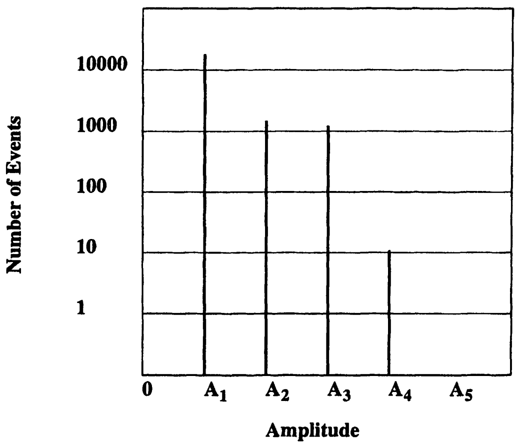

FIG. 17. Cumulative amplitude distribution of pulse heights. As shown here, 10 events have amplitudes exceeding A_4; 1010 have amplitudes exceeding A_3; 1110 have amplitudes exceeding A_2; and 11 110 have amplitudes exceeding A_1.

available for virtually instant monitoring and interpretation.

7.3 Applications

The effectiveness of AET has been well demonstrated in tests such as those dealing with the integrity of fiberglass storage tanks and pressure vessels (Pollock, 1989). In the 1970s the chemical industry was experiencing failures of fiberglass storage vessels. After the practice of AET of storage vessels was instituted by one manufacturer, the tank failure problem was eliminated. Another example of AET is its use during welding operations. Computer algorithms now exist that recognize various characteristics of acoustic-emission signals during the process of resistance welding and can control the welding current in a preprogrammed manner. AET has also been used for in-flight monitoring of aircraft (Scott, 1991).

In general, there are several features that have made AET attractive:

1. It can often be carried out while the unit tested is in normal operation.
2. Access to the whole structure is not required.
3. AET can highlight regions that are potential trouble spots, so that these can be examined in detail by other NDT methods.
4. AET responds to the behavior of materials under mechanical stress, no matter how this stress is produced—mechanical, thermal, or chemical.
5. There are no restrictions on such material properties as conductivity or magnetic permeability.

8. OTHER NDT PROCEDURES

This section lists and briefly describes NDT techniques that were not treated in earlier sections. Some of these are quite specialized; others have been demonstrated in the laboratory but have not yet found wide application.

If there are NDT procedures that are in existence but have not been mentioned in this article, the omission is unintentional and is regretted, with apologies to the developers of these procedures.

8.1 Strain Gauge

The use of strain gauges is not generally a flaw-finding technique, but a method of determining the state of strain in a surface, to determine experimentally the degree of safety in the operation of a mechanical structure. A strain gauge, fabricated of wire and thin layers of metal foil and bonded to a surface, measures strain by changes in its electrical resistance (Window and Holister, 1982).

8.2 Photoelasticity

This visual means for studying the results of applying various amounts of stress to an object makes use of the property of birefringence of some transparent materials when strained, to result in fringes that reveal strain patterns. The technique can be used with a model sheet of transparent material for design studies. For actual objects, the transparent material is bonded to a polished surface of the object as a transparent plastic coating, and the fringe, or strain pattern, is seen by reflection (Zandman *et al.*, 1977).

8.3 Brittle Coating

Fractures that occur in a thin coating that has been applied to a surface when a specimen is stressed indicate magnitudes and directions of strains in the surface (McMaster, 1959; Lineback, 1989).

8.4 Replication

The contours of a surface of a component are replicated by impressions with materials such as cellulose acetate or silicone. These impressions are observed and irregularities are quantified under examination with optical or electron microscopes, to attempt to predict the useful life of the component (McMaster, 1959; Marder, 1989).

8.5 Volatile-Liquid Method of Surface Crack Detection

In this simple technique of detecting regions of porosity or surface cracks, a volatile liquid is applied to the surface of a test piece. When the latter is heated, the liquid evaporates, leaving regions of porosity or spots with surface cracks colored or shaded (Oaks, 1972).

8.6 Leak Detection

The techniques of leak detection are aimed at finding microscopic channels or cracks in the walls of a volume that are supposed to be impervious to any gas transfer (McMaster, 1982a). The following techniques are in use.

8.6.1 Tracer-Gas Method This method is applicable to any structure that can be sealed, to become a closed vessel except for vacuum pumping through an orifice. This "closed vessel" is now vacuum pumped continuously through the orifice. To find a leak, helium is sprayed around the outside of the closed vessel while any gas remaining in the vessel is being examined for helium content by a mass spectrometer system. If sufficient helium is detected to sound an alarm, a leak exists in the wall of the structure in the vicinity of the location where the helium is being sprayed.

8.6.2 Sealed Package, Holographic Method A leak in a sealed package can be found by detecting small changes in the package dimensions by a holographic method (see Sec. 8.21).

8.7 Radioactive-Gas Penetrant

This method has been used to detect pores and cracks in the surface of a solid. When a radioactive gas such as krypton-85 is applied to the surface, some of the gas is absorbed in surface cracks or pores. Beta or gamma radiation emitted by this absorbed gas exposes x-ray–sensitive film placed on the surface, thereby generating a map of surface cracks and pores (Packer *et al.*, 1967).

8.8 Acoustic Impact Response

To search for cracks, debonding, and delaminating, an object under test is struck a blow with a hammer and the acoustic/vibrational transient response is compared with the response of a "perfect specimen" that has been struck in the same manner (Schroeer *et al.*, 1970).

8.9 Sonic Testing of Composite Structures

8.9.1 The Sonic-Resonator Method Flaws in a structure, such as disbonds, are detected by measuring the input impedance Z_{in} at audio frequencies to a piezoelectric transducer that is bonded to the structure and comparing this Z_{in} to that of a standard (Botsco, 1966).

8.9.2 The Eddy Sonic Method By setting up eddy currents of the frequency range 2–10 kHz in a partially electrically conducting structure, mechanical forces, and consequent vibrations at the eddy-current frequency, are created. Flaws are detected by monitoring the sonic output vs. frequency and comparing this with the output from a standard (Botsco, 1968).

8.10 Thermal Techniques

8.10.1 Temperature Mapping during Operation of Test Piece A temperature map of one or more of the surfaces of equipment during its actual operation can reveal regions whose temperature is excessive for safe operation. Such a map can be obtained by covering a surface with a film of liquid crystal or other types of material whose color is temperature sensitive, by the use of pyroelectric instruments, or by sensing and mapping the local thermal radiation emitted (McGonnagle, 1966; Brown, 1968).

8.10.2 Surface Flaw Detection by Scanning with a Heat Pulse Surface or near-surface flaws can be detected by scanning a surface with a pulse of heat and measuring the transient temperature rise in the vicinity of this scanning heat pulse. In the work that demonstrated this technique, the heat pulse was the heat from a watt-level laser beam; the transient temperature rise was obtained by measuring the far-infrared radiation emitted (Kaufman *et al.*, 1987).

8.11 Electric-Current Injection

Cracks, corrosion, or other flaws that reflect as irregularities of conductivity in bodies of regular shape of electrically conducting material, such as rail lines, can be found by resistance measurements by a four-point-probe method (Buchanan and Thurston, 1956).

8.12 Static Magnetic Field

Measurement of the local external magnetic-field intensity of magnetized ferromagnetic specimens of uniform and regular shapes can reveal the presence of surface cracks, subsurface discontinuities, and depths of case hardening. The technique can also be used to measure the thickness of nonmagnetic coating by comparison with a standard (Gardner and Barton, 1970).

8.13 Corona Discharge

The intent of this technique is to detect a void in dielectric material, such as in the insulation of cables or in glass-epoxy material. An imposed electric field of sufficiently high intensity ionizes the gas in the void, and electrons are accelerated to the wall of the void. The void can be detected either by the minute pulse of current in the secondary of the high-voltage transformer supplying the electric field or by the electromagnetic spectrum radiated (Dakin and Lim, 1957; Hendron *et al.*, 1964).

8.14 Capacitance Measurement

To check dielectric materials for leaky paths, electrodes are applied, and the capacitance and loss factor are measured and compared to a standard (Zubrick, 1968).

8.15 Microwaves

Microwaves, i.e., electromagnetic waves of range 1–100 GHz, can be used to measure the thickness of plates, as well as to locate voids and inclusions in dielectrics and cracks in metal surfaces, by measurement of changes in phase, amplitude, and polarization of transmitted or reflected waves (Bahr, 1982; Ida, 1992).

8.16 YIG Resonator

A sensitive method of detecting cracks in metal surfaces depends on observing the change in the ferrimagnetic resonance frequency of a small yttrium iron garnet sphere as it is moved along the surface (Auld, 1977, 1978).

8.17 Nuclear Magnetic Resonance Imaging (NMRI)

NMRI, the technique based on mapping local composition in the bulk of a substance by observing nuclear magnetic resonance frequencies and relaxation times in a spatially varying magnetic field, now a well-established procedure of medical diagnostics, can also be used to map composition and defects of spatial structure of materials (Listerud *et al.*, 1989; Sarkar and Komoroski, 1992).

8.18 Barkhausen-Noise Analysis (BNA)

When the magnetic-field intensity applied to a ferromagnetic material is swept smoothly up or down through a range of values, the magnetic-flux density changes in minute steps. A coil adjacent to the material translates these steps into voltage pulses. Signal analysis of these noise pulses reveals information about microstructural parameters of the material, stresses, fatigue, and creep damage (Sundstroem and Poerroenen, 1979).

8.19 Radiometric Surface Crack Detection in Moving Surfaces

Since a crack in a surface appears black, it has an emissivity for thermal radiation of virtually unity. This is generally higher than the emissivity of a surface. A crack in a moving surface can therefore be detected by monitoring the instantaneous thermal radiation received by a detector as the surface passes in front of it. (For a surface at room temperature, the detector must be sensitive to far-infrared radiation.) Changes in the pattern of the detected signal over a period of time indicate changes in the surface, such as the formation of new cracks (Kaufman and Choudhury, 1985).

8.20 Speckle Metrology

The speckle pattern of the reflected light that is seen when an optically rough surface is illuminated with highly coherent light can be used to measure displacements, detect cracks, and perform vibrational analysis (Sirohi, 1993).

8.21 Optical-Holography Interference Method

A holographic image of an object is stored on film. When this image is made to interfere optically with another holographic image that was taken while the body was stressed, or with the body itself, contour lines reveal surface displacements caused by such flaws as surface or internal cracks, or debonding (Erf, 1974; Vest, 1986).

8.22 Optical-Holography Vibrational Analysis

A hologram of an object taken while the object is vibrationally excited at some audio frequency yields a "time average" fringe pattern. Changes in internal structure are detected by comparison of this fringe pattern with that of a hologram recorded earlier with the same vibrational excitation (Powell and Stetson, 1965; Stetson, 1974).

8.23 Ultrasonic Holography

Ultrasonic holography substitutes ultrasonic acoustic waves for light waves, with the advantage of being able to "see" inside of opaque objects. Two basic ways of forming ultrasonic holograms exist:

1. an optical-analog scheme, in which surface displacements of a liquid surface, formed by interfering acoustic waves, are sensed optically and converted to an optical image;
2. point-by-point wave-front sampling by a moving transducer or by a number of transducers, with ultimate conversion to an optical image.

Ultrasonic holographic techniques offer the possibility of being a supplement to ordinary ultrasonic NDT, in which the latter can *find* defects, while acoustic holography can size them to an accuracy of 1–3 mm, even to a depth in steel of 30 cm (Szilard, 1982).

8.24 Acoustic Microscopy

With acoustic waves of frequencies in the range of 300 MHz and higher, pulse lengths of a few nanoseconds, and quasi-optical focusing techniques, internal and surface geometries of microscopic dimensions in test specimens can be sensed and converted to visual images (Briggs, 1995).

8.25 Exoelectron Emission from Metals

Emission of electrons in high vacuum, particularly if a surface is scanned by a spot of ultraviolet light, has been reported to provide quantitative measurements of distribution and extent of fatigue damage prior to formation of a fatigue crack (Hoenig *et al.*, 1971).

8.26 Compton-Scattered Radiography

This x-ray or gamma-ray technique is based on imaging the scattered, lower-energy photons resulting from Compton-scattering collisions. Since Compton collisions allow back-scattering, x-ray imaging with access to only one side of a specimen is possible. This suggests such applications as detecting and locating steel inside a concrete wall (Harding *et al.*, 1983/84).

8.27 Energy-Loss Ion Radiography

When finely focused beams of ions in the 1- to 5-MeV range are transmitted through thin slices of material, their energy loss suffered during the transmission can provide information of the material passed through. By rastering such a beam across a specimen, an area display similar to an x-ray radiograph can be obtained (Overley *et al.*, 1983).

8.28 Neutron Radiography

Neutron radiography complements x-ray or gamma-ray NDT by being insensitive to the presence of metals and, instead, revealing the presence of hydrogenous material. It can therefore be used for finding hydrogenous corrosion products; detecting rubber, plastics, and explosives; and imaging masses of these substances and finding imperfections in them (Bromley, 1983).

8.29 Positron Annihilation

When positrons are injected into a material from a radioactive source, they annihilate themselves by combining with electrons and generating gamma rays. Their mean lifetime before annihilation has been found to depend on the presence of microscopic defects. They can therefore be used to locate microscopic defects in situations where plastic deformation, fatigue cycling, or creep exist (Grosskreutz and Millet, 1969).

8.30 Tomographic Imaging

This covers the general technique of mapping the distribution of some material property inside a structure by finding the two-dimensional distributions in what are essentially "slices" of the structure. An example is the well-known CAT scan referred to in Sec. 4. Methods used include scanning with x rays (for material density), ultrasonic waves (for elastic properties), neutrons (for determining nuclei distribution), ions (for material density), and nuclear magnetic resonance (for nuclear-spin density and relaxation times) (Kuhl and Edwards, 1963; Hounsfield, 1973; Pontau *et al.*, 1989). The most successful of these methods, used extensively for medical diagnosis, are x-ray CAT scans, referred to in Sec. 4, and NMRI, of Sec. 8.17.

8.31 Surface-Crack Detection by Optical Scanning

Detection and mapping of surface cracks, measurement of crack width, and a pictorial display of cracks, even in a rough surface, by scanning with an optical beam make use of the fact that specular reflection in a fixed direction of a light-beam incident on a surface is interrupted by a crack (Chang *et al.*, 1987).

GLOSSARY

Acoustic Emission: The generation of transient acoustic waves by local rapid release of stored elastic energy during stress-induced irreversible structure changes.

Acoustic Waves: Also called "elastic waves." Mechanical waves that can propagate in liquids and solids by energy exchange between stress–strain potential energy and kinetic energy of particle motion.

A-Scan: From the pulse-echo method of ultrasonic NDT, display of echo signals vs. time that shows the location of sources of echoes and their relative magnitudes along a line that extends outward from the transducer into the specimen under test.

Barkhausen Noise: Small voltage pulses developed by a coil adjacent to a ferromagnetic material when an applied magnetic-field intensity is swept slowly through a range of values.

Borescope: Slender, straight-tube periscope or flexible fiber-optic system, used to visually inspect the interior of hollow components for defects.

B-Scan: For the pulse-echo method of ultrasonic NDT, a two-dimensional map of sources of echoes in the cross section of a specimen. Echo intensity can be indicated by relative brightness or by color.

Buildup: In radiographic NDT, undesirable fogging of x-ray film by radiation arising from Compton scattering in the test specimen.

Bulk Waves: Waves within a material specimen that do not depend on shape and dimensions of the body in which they propagate.

CAT Scan: See **Computer-Aided Tomography.**

Characteristic Impedance Z_0: A constant of a wave transmission system. It is a function of material properties and structure and determines relative amplitudes and phases of reflected and transmitted waves when waves arrive from another material or wave transmission system.

C-Scan: For the pulse-echo method of ultrasonic NDT, a two-dimensional map of the distribution of sources of echoes parallel to and beneath the surface of the item under test. Echo intensity can be indicated by relative brightness or by color.

Compton Scattering: Deflection from original path and reduction in energy of an x-ray photon by collision with a weakly bound electron.

Critical Angle of Incidence: The minimum angle of incidence of an acoustic wave that causes total reflection at a boundary between two media.

Decohesion: A brittle fracture, associated with rupture along grain boundaries.

Developer: In photography, a chemical that causes a latent image on a film to become a visible image. In liquid-penetrant inspection, a fine powder that aids in highlighting cracks by drawing colored or fluorescent fluid out of them.

Direct Type Film: A type of x-ray film, also called "nonscreen type," that is fabricated with a thin metal foil in contact with the emulsion.

Eddy Currents: Circulating currents in electrically conducting material caused by magnetic fields of time-varying currents flowing in adjacent conductors.

Elastic Waves: See **Acoustic Waves.**

Electromagnetic Coupling: Coupling between two systems by electromagnetic fields. In ultrasonic NDT this term means coupling between an electric circuit and acoustic waves in an electrically conducting test piece immersed in a magnetic field because of the Lorentz force $\mathbf{j} \times \mathbf{B}$.

Electrostatic Coupling: In ultrasonic NDT of a metal specimen, generation or detection of acoustic waves by utilization of the force on a conductor in an electric field.

Film Density, *D*: For a small spot of photographic or x-ray film that has been exposed and developed, $D = \log_{10}$ (intensity of light incident on film/intensity of light transmitted through film).

Film Gradient, G_D: Measure of film sensitivity to changes in incident light (or x-ray) level. G_D is slope of curve of film density D when plotted as a function of $\log_{10}E$, where E is the product of light (or x-ray) intensity and film exposure time.

Film Speed: Measure of relative sensitivity of a particular film. Example: To produce the same degree of blackening with the same incident light intensity, a film of speed 200 requires only half the exposure time of that required by a film of speed 100.

Fluoroscopy: Conversion of a radiographic image into a visible-light image by causing the radiation that has passed through a test specimen to impinge on a screen that emits visible light when struck by x rays or gamma rays.

Fracture Mechanics: Analysis of structures, to predict the degree of loading that will cause failure. Example: Study of the load-carrying capacity of a structure in the presence of an initial defect, such as a dominant crack.

Frame Averaging: Clarification of an image through a filtering technique based on averaging several image frames.

Half-Value Layer, HVL: The thickness of a material that reduces the intensity of radiation passing through this material to one-half of the incident value.

Image Quality Indicator, IQI: In radiographic NDT, fixture placed between x-ray source and specimen under test, to measure the minimum size of flaw that can be detected; also called "penetrameter."

Lamb Wave: An acoustic wave that can propagate in a thin solid sheet.

Leakage Field: The external magnetic field adjacent to the surface of a magnetized body in the vicinity of a surface crack or shallow subsurface defect.

Lift-Off Effect: In eddy-current testing, change in test coil impedance caused by separation of coil from specimen.

Liquid Penetrant: A liquid used to coat a surface in order to reveal cracks.

Longitudinal Wave: Acoustic wave in which particle motion is parallel to the direction of propagation.

Love Wave: An acoustic surface wave that can propagate on a solid covered with a thin layer of material of different density than that of the solid that it covers.

Magnetic Domain: A region in a solid within which elementary magnetic moments have arranged themselves parallel.

Magnetostriction: The mechanical strain developed in a ferromagnetic material on the application of a magnetic-field intensity.

Magnetic-Particle Inspection: Technique of searching for surface or shallow subsurface flaws of a magnetized ferromagnetic body by applying small iron particles and looking for spots on the surface where they accumulate.

Mode Conversion: The coupling of energy from one type of wave propagation to another one. Example: Conversion of a portion of the energy of a longitudinal to a transverse acoustic wave.

Nondestructive Evaluation, NDE: The procedure of examining a structure without damaging it, followed by evaluation of test results.

Nondestructive Inspection, NDI: The actual procedure of testing a structure.

Nondestructive testing, NDT: The procedure of examining a structure without damaging it. In the present article the initials NDT are used to include NDE and NDI.

Noninvasive: Procedure in which there is no penetration of the surface of a body or structure by a physical object.

Nonscreen Type Film: See **Direct Type Film.**

Penetrameter: Image quality indicator in radiographic NDT. See **Image Quality Indicator.**

Penumbra: Partially illuminated space between regions of perfect shadow and of full illumination. The penumbra regions in radiographic images set a limit on image resolving power.

Piezoelectric: Materials that are piezoelectric will generate electric polarization, and therefore electric fields, when mechanically strained. Conversely, they can become locally strained when placed in regions of electric field.

Plastic Deformation: Permanent change in shape or size of a solid body when it is subjected to a stress exceeding a particular value.

Pulse Echo: In ultrasonic NDT, the method of sending out short acoustic pulses and locating flaws and other irregularities by noting directions, times of arrival, and amplitudes of echoes.

Radiography: The science and technology of using x rays or gamma rays for imaging and analyzing internal structure of materials or organisms. The more common term used when dealing with living organisms is "radiology."

Radiometry: The technique of using spontaneous radiation emitted by a body or an area, sometimes called "blackbody radiation," to measure temperature or to map the area.

Radioscopy: The technique of creating analog images for continuous viewing of the results while a specimen is being illuminated with x rays or gamma rays.

Rayleigh Waves: Acoustic waves that propagate on smooth surfaces and can be used to detect surface or shallow subsurface defects. Rayleigh waves have also been developed to carry out high-frequency analog signal processing.

Remanence, Remanent Magnetization: The amount of magnetization remaining in a ferromagnetic structure after an impressed magnetic-field intensity that caused a net magnetization to exist has been removed. In practice, the remanence is the magnetization that remains after the exciting current in a coil surrounding the structure has been set equal to zero.

Resolving Power: A quantitative measure of the ability of an optical instrument to produce separable images.

Salt Screen Film: X-ray film whose emulsion is coated with a fluorescent powder that emits ultraviolet radiation when struck by x rays, thereby reducing needed exposure time, but at the expense of resolving power. Also called "screen-type film."

Scintillating Material: Materials such as NaI(Tl) that emit light when struck by x rays.

Screen-Type Film: See **Salt Screen Film.**

Shear Waves: Acoustic waves for which the particle motion is perpendicular to the direction of propagation. Also called transverse waves.

Skin Depth: For transverse electromagnetic waves propagating into a material, the depth at which the field intensity has decayed to 0.36787 of its value at the surface.

Spatial Filtering: In processing optical signals, the techniques of discriminating between various rates of spatial change (lines per mm) in light intensity.

Stonely Wave: An acoustic wave that can propagate along the interface of two different materials.

Tomography: The recording of internal structure of a body at a particular plane while blurring detail in other planes.

Transducer: A fixture or structure that converts energy from one type of distribution to another, or from one type of energy to another. Respective examples are radio antennas and the piezoelectric wafers used in ultrasonic NDT.

Transverse Waves: See **Shear Waves.**

Twinning: A process in which a portion of a crystal assumes an orientation that is symmetrically related to the basic crystal orientation.

Ultrasonic NDT: The method of NDT that is based on the use of acoustic waves whose frequencies lie in the ultrasonic range.

Unsharpness: An expression used in radiographic NDT to describe the amount of blur in the image of a specimen.

White Noise: A random signal whose power per unit frequency increment (up to some undefined high frequency) is the same for all frequencies.

INTRODUCTION

The electrical, thermal, optical, magnetic, and mechanical properties of materials are significantly dependent on its microstructure, i.e., structure of the material on a microscopic scale. All materials when examined at an atomic scale contain a large number of imperfections or defects, which have a profound effect on the behavior of the material. Typically, microstructural defects occur when atoms are displaced from their crystallographic lattice sites or when foreign atoms occupy lattice and nonlattice sites. The dimensions of the defects range from atomic size (point defects) to large extended defects such as grain boundaries, dislocations, stacking faults, voids, clusters, precipitates, etc. The properties of the materials are profoundly sensitive to these microstructural defects. The influence of defects on material properties is not always adverse, and often specific properties can be deliberately fashioned by controlled introduction of particular defects. For example, defects in semiconductor materials act as trapping sites for electron and hole transport, thereby significantly degrading the transport and optical properties and device performance, whereas controlled defects such as precipitates are introduced in metallic alloys to increase their yield strength. Thus, a controlled creation of microstructural defects may result in the formation of stronger metals and intermetallic alloys, long-lifetime lasers and light-emitting diodes, superconductors with enhanced current-carrying abilities, faster and more densely packed electronic circuits, more powerful magnets, and many other materials of practical importance.

One of the easiest and most widely used methods to alter and control the microstructure and crystalline defects in materials is to perform an elevated-temperature heat treatment or "thermal annealing" for an extended period of time. The annealing treatment is primarily meant to alter the microstructure,

produce a specific microstructure, and alter stresses and defect concentrations in the materials. Thermal annealing of materials is typically conducted in an isothermal, cylindrical or box furnace that is heated by resistive elements. The temperature and the ramp rate of the furnace can be precisely controlled. The near-equilibrium conductive, convective, and radiative heat transfer from the heating elements to the workpiece ensures isothermal heating of the materials with a high degree of precision in thermal uniformity. When the temperature of the material is increased, the motion of the atoms is significantly enhanced. This allows the atoms to migrate to the lattice sites. The stabilities of different defects are not the same; some defects can be annealed out at moderate temperatures (600–800 °C), while in other cases even very high temperatures (1000–1300 °C) may not be sufficient for complete defect removal. Thus the understanding of the thermal stability of defects is critical for controlling the microstructural development during the thermal processing of a given material.

Thermal annealing of materials may not only produce desirable changes in microstructure, but may also lead to unwanted effects such as precipitate growth in metals, dopant diffusion in semiconductors, and thin-film reactions in superconducting thin films. For example, an optimum goal for any silicon-based–semiconductor annealing process is to remove defects to ensure substitutional incorporation of the dopants so that a high degree of dopant activation and higher mobility of the carriers can be achieved. Besides obtaining these desirable properties, the annealing process should minimize unwanted effects such as dopant diffusion, which is especially critical for the next generation of very large-scale integrated (VLSI) circuits. In metal processing, the heat treatment reduces defects like dislocation density to improve ductility and reduce stress, but this treatment also causes grain growth, which results in detrimental mechanical properties. Thus, the optimization of the thermal annealing parameters (temperature, residence time, and gas environment) is an important engineering challenge. An overview of the critical issues related to application of thermal annealing to various material systems such as metals, semiconductors, ceramics, and high-temperature superconductors follows.

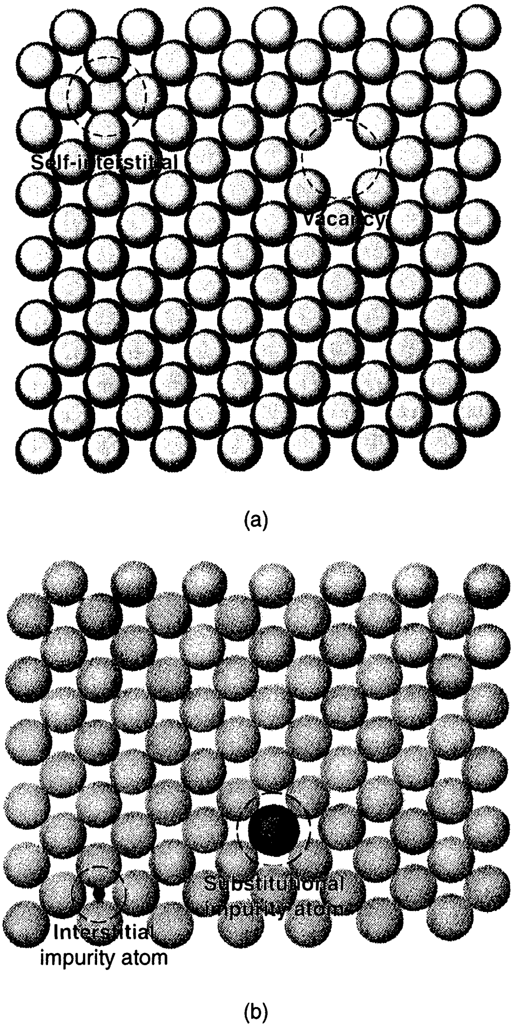
1. DEFECTS IN MATERIALS

A brief description of crystalline imperfections in solids has been provided in this section in order to understand the annealing processes and mechanisms of annealing in a better way. Solid materials may be classified according to the regularity in which the atoms or ions are arranged with respect to one another. A *crystalline material* is one in which the atoms are situated in a repeating or periodic array over large atomic distances; i.e., long-range ordering exists. To define the long-range ordering the term *lattice* is used in context of crystal structures. The term lattice means a three-dimensional array of points coinciding with the atom positions. For a crystalline solid, when the periodic and repeated arrangement in atoms is perfect and exists through the entirety of the specimen without interruption, the substance is called a *single crystal.* In a single crystal, the atoms have the same periodic structure or orientation throughout the whole specimen. Most crystalline solids are composed of a collection of small crystals or *grains;* such materials are termed *polycrystalline.* Thus throughout a grain, the material has the same crystallographic orientation. This orientation varies from grain to grain. Because of varying crystallographic orientation between grains, there exists an atomic mismatch within the region where two grains meet; this area is called the *grain boundary.* If a sufficient number of atoms are displaced from their lattice sites such that there is no long-range ordering, the material becomes *amorphous* or *noncrystalline.*

Any departure from the three-dimensional lattice grid represents a defect in the material. A crystalline defect is a lattice irregularity of the scale of atomic size in one or more dimensions. The classification of crystalline imperfections is made according to the geometry and the dimensionality of the crystalline imperfection. Thus one has point defects (associated with one of two atomic positions), linear (one-dimensional) defects such as *dislocations*, or two-dimensional defects such as *interfaces* and grain boundaries. See POINT AND EXTENDED DEFECTS IN CRYSTALS.

1.1 Point Defects

Point defects play a very significant role during thermal annealing of materials. Figure 1 shows some of the defects that are commonly observed in nonionic solids (metals, semiconductors, and covalently bonded ceramics). The simplest form of point defects is a vacancy, or a vacant lattice site that is normally occupied by the host atom. Thermodynamically an equilibrium concentration of vacancies exists at any given temperature; their concentration increases with increasing temperature. An interstitial atom is one crowded into the small space between lattice sites. If the interstitial atom is an atom from the crystal itself, it is called self-interstitial. Other types of point defect are formed when foreign atoms (impurities) are incorporated into the crystal. The impurity point defects can be either substitutional or interstitial. For substitutional, the impurity point defect replaces the host atom, while an interstitial atom fills the voids or interstices of the host atoms.



(a)

(b)

FIG. 1. Two-dimensional schematic representations of (a) a vacancy and self-interstitials and (b) substitutional and interstitial impurity atoms.

Atomic point defects in oxides or ceramic compounds become more complicated because two or more types of crystal sublattice exist in these materials. For example, in MgO, magnesium interstitials and vacancies and oxygen interstitials and vacancies may exist. As a consequence of electroneutrality, defects in ceramics may occur in pairs. One such type of defect involves a cation vacancy and a cation–interstitial pair and is termed the Frenkel defect (Fig. 2). A Schottky defect is a cation-vacancy, anion-vacancy pair, which is created by removing one cation and one anion from the interior of the crystal and placing them both at the external surface (Fig. 2).

1.2 Extended Defects

Defects that possess at least one dimension extending to large lengths (greater than several crystal lattice spacings) can be termed extended defects. A dislocation is a linear or one-dimensional defect around which some of the atoms are misaligned. One type of dislocation is represented in Fig. 3(a): an extra half-plane of atoms, the edge of which terminates within the crystal. This edge is termed the dislocation line, which in the case of edge dislocations is perpendicular to the plane of the page. Another type of dislocation is called the screw dislocation, shown in Fig. 3(b), in which the atomic distortion is linear along the dislocation line. Many dislocations in materials are mixed with some component being screw and the rest being edge type. In metals and to a lesser degree in semiconductors, the dislocations can move with the application of mechanical stress and thus are significantly involved in the plastic deformation of crystalline materials. The ductility (or the brittleness) of materials depends on the ability or inability of the dislocations to move.

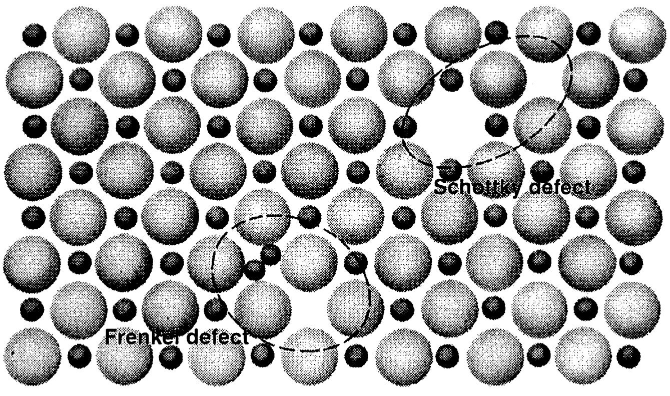


FIG. 2. Schematic diagram showing Frenkel and Schottky defects in ionic solids.

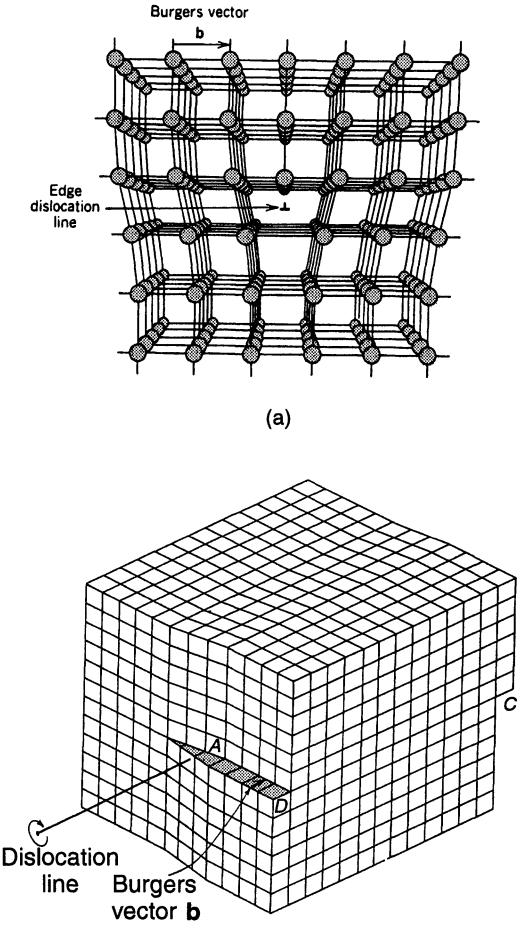

FIG. 3. Schematics of (a) an edge dislocation and (b) a screw dislocation within a crystal.

High-temperature annealing facilitates the movement of dislocations and can accelerate the annihilation process. In ceramic materials, dislocations are not mobile even at high temperatures and therefore do not play a significant role in the annealing process.

Another interfacial defect that plays a critical role in the annealing process is the grain boundary [Fig. 4(a)], which corresponds to the boundary separating two grains of different crystallographic orientation (see GRAIN BOUNDARIES). Within the boundary region, which is approximately a few atomic spacings wide, there is atomic mismatch due to transition from one crystallographic orientation to another. When the angular mismatch is small, on the order of a few degrees, then the term low-angle grain boundary is used. During thermal annealing, the grains increase in size or coarsen, resulting in a decrease in the total boundary energy. There is another type of grain boundary that exists commonly in many crystals, the twin boundary. A twin boundary is a special type of grain boundary across which there is a specific mirror lattice symmetry; i.e., atoms on one side of the boundary are located in mirror-image positions of the atoms on the other side [Fig. 4(b)]. Twins occur on a definite crystallographic orientation plane and in a specific direction, both of which depend on the crystal structure. Twins result from atomic displacement and are produced from applied mechanical shear forces (mechanical twins) or during annealing heat treatment

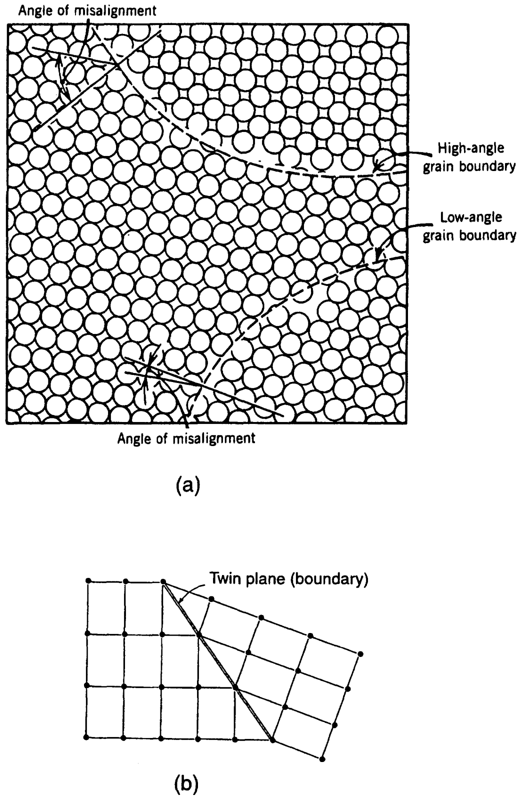

FIG. 4. Schematic diagram showing (a) low- and high-angle grain boundaries and (b) a twin boundary.

(annealing twins). Another type of defect that is important in metals, semiconductors, and superconductors is the stacking fault, which is formed when the stacking sequence of the close-packed planes is interrupted.

2. ANNEALING OF METALS

Annealing of metals is mostly used to eliminate the effect of cold working and to restore the cold-worked metal to the original soft, ductile condition. A variety of annealing heat treatments are possible, characterized by the changes that are induced. These changes are mostly related to microstructure resulting in the alteration of mechanical properties. The annealing process consists of three stages:

1. heating to the desired temperature,
2. holding at that temperature, and
3. cooling, usually to room temperature.

During annealing, diffusional processes are normally active. Therefore, temperature is an important consideration to accelerate the annealing process. Time is also an important parameter in these procedures as the actual annealing time must be long enough to allow for any necessary transformation reactions, particularly if the reaction involves diffusion. During heating and cooling, there exist temperature gradients between the outside and interior portion of the piece. The magnitudes of temperature gradients depend on the size and shape of the piece. If cooling is too fast or the rate of temperature change is too great, the temperature gradients cause internal stresses that may lead to warping or even cracking.

2.1 Annealing Procedure

Because of the technical importance and complexity of iron-based alloys, annealing procedure of only this system is discussed in the present article. However, many features associated with the annealing of iron-based alloys are common to annealing of other metals also (Clarebrough *et al.*, 1955). The main purpose of an annealing procedure is to enhance certain properties of steel alloys. Therefore, the annealing cycle and temperature of iron-based alloys should be designed in such a manner that the process results in the realization of steels with the optimum properties. The iron–iron-carbide phase diagram shown in Fig. 5 helps one to understand the annealing procedures more conveniently. The horizontal line at the eutectoid (three-phase reaction in which one solid phase transforms to two different solid phases) temperature, conventionally labeled A_1, is termed the *lower critical temperature,* below which, under equilibrium conditions, all austenite will have transformed into ferrite and cementite phases (see STEEL). Austenite is a face-centered-cubic iron or steel alloy. The phase boundaries denoted as A_3 and A_{cm} represent the upper critical temperature lines for hypoeutectoid and hypereutectoid steels, respectively. Hypo- and hypereutectoid refer to alloys for which the concentration of solute is less and greater than the eutectoid composition, respectively. For temperatures and compositions above these boundaries, only the austenite phase prevails.

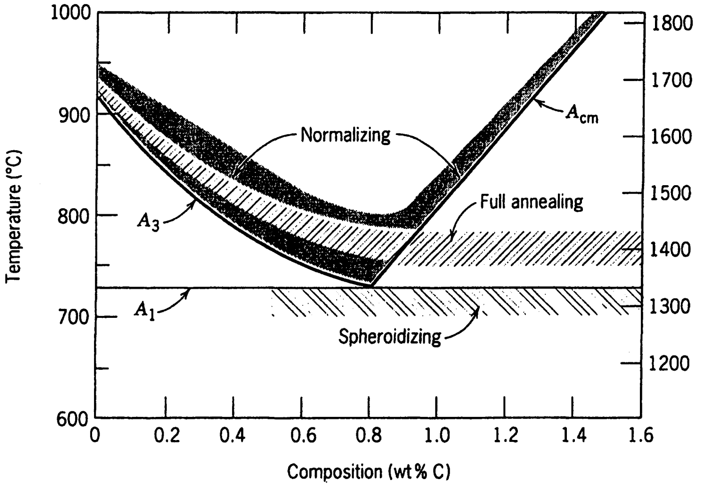

FIG. 5. The labeling of phase boundaries in the iron–iron-carbide phase diagram in the vicinity of the eutectoid indicating heat-treating temperature ranges for plain carbon steels. (Adapted from Lyman, 1948.)

2.1.1 Normalizing It has been commonly found that steels deformed plastically by a rolling operation consist of grains of pearlite, which are irregularly shaped and relatively large, but varying substantially in size. An annealing heat treatment called *normalizing* is used to refine the grains (i.e., to decrease the average grain size) and produce a more uniform and desirable size distribution. It is worth mentioning here that pearlitic steels are tougher than coarse-grained ones. Normalizing is accomplished by heating at approximately 55–85 °C above the upper critical temperature, which is dependent on composition as indicated in Fig. 5. After sufficient time has been allowed for the alloy to completely transform to austenite, the treatment is terminated by cooling in air.

2.1.2 Full Annealing A heat treatment known as *full annealing* is often utilized in low- and medium-carbon steels that will be machined or will experience extensive plastic deformation during a formation operation. The alloy is austenitized by heating to 15–45 °C above the A_3 or A_1 lines in Fig. 5 until equilibrium is achieved. The alloy is then furnace cooled for several hours. The microstructural product of this anneal is coarse pearlite that is relatively soft and ductile. Although the full-anneal cooling procedure is time-consuming, it yields a microstructure having small grains and uniform grain structure.

2.1.3 Spheroidizing Medium- and high-carbon steels, which may contain coarse pearlite, can still be too hard to machine or plastically deform conveniently. These steels may be annealed to develop the spheroidite structure. Spheroidized steels have a maximum softness and ductility and are easily machined or deformed. The spheroidizing heat treatment consists of heating the alloy at a temperature just below the eutectoid line A_1 in Fig. 5.

2.2 Stress Relief, Recrystallization, and Grain Growth

The original cold-worked microstructures of metals consist of deformed grains containing a large number of tangled dislocations. When the metal is first heat treated at low temperatures (low-temperature treatment is called recovery), the thermal energy forces the dislocations to move and form the boundaries of a polygonized subgrain structure. The density of dislocations, however, remains the same as shown schematically in Fig. 6. Because the number of dislocations is not changed during recovery, the mechanical properties remain practically unchanged. However, residual stresses are reduced or even eliminated when the dislocations are rearranged. During this annealing, the high electrical conductivity of the metal is also restored.

Recrystallization occurs by the nucleation and growth of new grains containing few

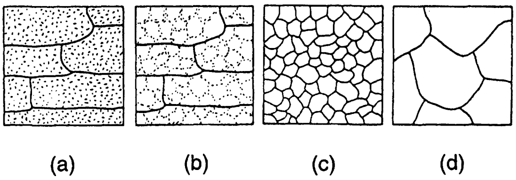

FIG. 6. The effect of annealing temperature on the microstructure of cold-worked metal; (a) cold worked, (b) after recovery, (c) after recrystallization, and (d) after grain growth.

dislocations. When the metal is heated above the recrystallization temperature, rapid recovery eliminates residual stresses and produces the polygonized dislocation structure. New grains then nucleate at the cell boundaries of the polygonized structure, eliminating most of the dislocations as shown in Fig. 6. Because of reduction in the number of dislocations, the recrystallized metal has a low strength but a high ductility.

At still higher annealing temperatures, both recovery and recrystallization occur rapidly producing the fine recrystallized grain structure. However, the energy associated with the large amount of grain-boundary area makes the fine structure unstable at high temperatures. To reduce this energy, the grains begin to grow, with favored grains consuming the smaller grains (Fig. 6). This phenomenon is called *grain growth.* A number of factors influence the size of the recrystallized grains. Reducing the annealing temperature, the time required to heat to the annealing temperature, or the annealing time will reduce the grain size by minimizing the opportunity for grain growth. Increasing the initial cold work also reduces the final grain size by providing a greater number of nucleation sites for new grains. Finally, the presence of a second phase in the microstructure helps prevent grain growth and keeps the recrystallized grain size small.

2.3 Factors Affecting the Properties of Steel

The optimum properties of a steel can be realized if during the quenching phase of the heat treatment, the specimen has been converted to high content of martensite. The formation of any pearlite and/or bainite will result in other than the best combination of mechanical characteristics. During the quenching process, it is impossible to cool the specimen at a uniform rate throughout the sample. The surface cools more rapidly than the interior regions, resulting in a possible variation of microstructure and properties with position within a specimen. The successful annealing of steels to produce the predominantly martensitic microstructure throughout the cross section depends primarily on alloy composition, type and character of the quenching medium, and size and shape of the specimen.

3. ANNEALING OF SEMICONDUCTORS

Defects in semiconductors act as trapping sites for electron and hole transport, thereby significantly degrading the transport properties and device performance. Point defects such as vacancies and interstitials can also significantly modify the diffusion characteristics of various impurities and dopants in the materials. Various semiconductor processing operations such as ion implantation, oxidation, lithography, and metallization create defects as a part of the process. In particular, ion implantation for dopant incorporation introduces a high density of defects. These defects range from point defects, Frenkel pairs, and dislocations to formation of amorphous layers and injection of interstitials, each of which can adversely affect device performance. The stability of defects controls the requirements of temperature and time of the annealing process. For example, amorphous thin films on surfaces requires low thermal budgets for crystallization and defect removal, whereas grain boundaries cannot be completely eliminated even by high-temperature annealing for extended time. Another example of incomplete removal of defects after thermal annealing is the solid-phase thermal annealing of ion-implanted silicon, leading to formation of a high density of extended defects such as dislocation loops, etc., which remain even after other defects have been removed.

Another important semiconductor thermal-annealing operation is solid-phase epitaxial (SPE) growth. Epitaxy refers to the ordered arrangement of atoms so as to mimic the structure of the substrate layer. Semiconductor materials are typically single-crystal in nature; thus annealing operations such as SPE growth are conducted so that the surface layer can be transformed into a single-crystal form. The SPE process occurs when a thin amorphous layer exists at the near-surface regions of the semiconductor. When the sample is annealed in a furnace at a fixed temperature, the amorphous layers reorder on the underlying single-crystal substrate. The thickness of the regrown layer increases linearly with time, thus indicating a constant growth velocity (see Fig. 7). The velocity can vary from 1 Å/s to 1 cm/s, depending on the processing temperature. This epitaxial ordering process occurs at temperatures much below the melting temperature. This is in sharp contrast to liquid-phase epitaxy, which occurs above melting temperature. The epitaxial regrowth velocity v_g can be expressed in form of an equation:

$$v_g = v_0 \exp(-E_a/kT), \tag{1}$$

where v_0 is called the preexponential factor and corresponds to 3.68×10^8 cm/s for ⟨100⟩ regrowth of silicon semiconductor. The activation energy for silicon has been determined to be $E_a = 2.76$ eV using this formula. In the case of silicon, the growth velocities in other directions have always been found to be lower than the [100] directions. The activation energy is approximately half of what is observed for dopant implantation. Thus SPE growth takes place at much lower processing temperatures. During the epitaxial growth process, implanted dopants move into substitutional lattice sites as the interfaces move past them. A second annealing treatment at high temperatures of 900–1000 °C is required to remove the residual defects in the material.

3.1 Diffusion Effects during Thermal Annealing

Concomitant with the removal of defects in thermal annealing, the redistribution of impurities is also observed after any thermal process. Typically, foreign atoms (called dopants) are incorporated into the semiconductor material via an ion-implantation process. The dopants make the semiconductor electrically active for formation of a useful electronic circuit. Dopants can be of two types: *p*-type like boron, which are positive carriers, and *n*-type like phosphorus, which are negative carriers. During the thermal annealing operation, significant diffusion of the dopants takes place. The implanted ion concentration can be described by a Gaussian function given by

$$C(x) = \frac{Q}{\sqrt{2\pi}\Delta R_p} \exp\left[\frac{-(x - R_p)^2}{2\Delta R_p^2}\right], \tag{2}$$

where Q is the dose, R_p is the projected-ion range, and ΔR_p is the range straggling. During heat treatment for dopant activation, the species are redistributed and the concentration $C(x)$ can be approximated by

$$C(x) = \frac{Q}{\sqrt{\pi(2\Delta R_p^2 + 4Dt)}} \left[\exp\left(\frac{-(x + R_p)^2}{2\Delta R_p^2 + 4Dt}\right) + \exp\left(\frac{-(x - R_p)^2}{2\Delta R_p^2 + 4Dt}\right)\right], \tag{3}$$

where D corresponds to the diffusion coefficient and t corresponds to the time. It is possible to make a quick estimate of the influence of the diffusion during annealing by comparing ΔR_p to the mass diffusion distance $(Dt)^{1/2}$. Figure 8 shows the composition profile of boron-implanted species after rapid thermal annealing (RTA). The as-implanted samples contain only dislocation loops with

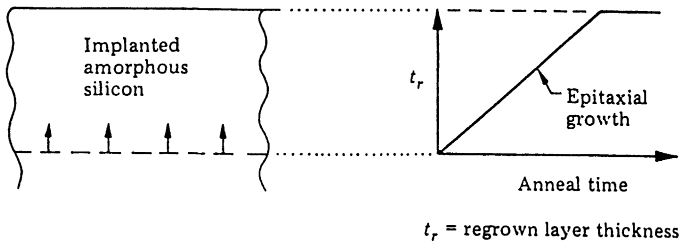

FIG. 7. Solid-phase epitaxial regrowth vs anneal time for an amorphous implanted layer on (100) Si.

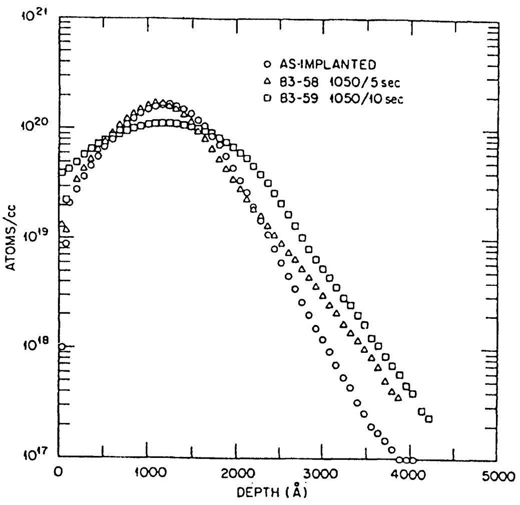

FIG. 8. Boron concentration profiles before and after annealing treatments for 5 and 10 at 1050 °C. (Adapted from Narayan *et al.*, 1984.)

a Gaussian profile peaked at 1180 Å. The figure shows that an average profile broadening of 100 Å is achieved after 1050 °C/(5 s) anneal, and increased to 330 Å after 1050 °C/(10 s) anneal.

3.2 Specialized Thermal Annealing Methods in Semiconductors

In semiconductor-based thermal annealing processes, elevated temperatures not only remove the damage but can also cause a number of unwanted effects such as dopant diffusion, thin-film reactions, etc. An optimum goal for any semiconductor annealing process is to remove the defects, while ensuring substitutional incorporation of the dopants so that a high degree of dopant activation and higher mobility of the carriers can be achieved. Besides obtaining these desirable properties, the annealing process should minimize unwanted effects such as dopant diffusion, which is especially critical for the next generation of VLSI circuits. In addition, in most semiconductors only the near-surface regions (<1 μm) represent the active device area; thus techniques that affect only the surface regions of a material can be applied. Section 3.2.1 deals with these different variations of standard furnace anneals that have been developed for semiconductor processing.

A schematic diagram of the processing temperature and the annealing times for each annealing method is shown in Fig. 9. Furnace annealing is typically conducted at temperatures of approximately 900 °C for several minutes, while in rapid thermal annealing (RTA) the wafer is typically heated to over 1000 °C for several seconds. In pulsed laser annealing (PLA), the maximum temperature is above the melting point of the silicon. However, the time scale for the whole process is less than 1 μs. Figure 10 shows different thermal methods for crystallization of amorphous layers in silicon. The figure shows that by use of either a furnace or a RTA system, solid-phase regrowth can be achieved, while in PLA the annealing phenomenon is accomplished by the formation of a thin melt layer on the surface. The depth of the melt controls the microstructure of the regrowth layer. If the melt depth is less than the thickness of the amorphous layer, polycrystalline surface regions are obtained. Table 1 lists the characteristics, advantages, and disadvantages of each of the annealing methods. As shown in this table, RTA represents the most promising method for systems that require low thermal budgets.

3.2.1 Furnace Annealing Furnace annealing has been the method of choice in the semiconductor industry since its inception. In this method the semiconductor wafers are placed in an isothermal cylindrical tube or box that is enclosed by an array of resistively heated elements. The temperature and the

ramp rate of the furnace can be precisely controlled. The near-equilibrium conductive, convective, and radiative heat transfer from the heating elements to the semiconductor ensures isothermal heating of the wafer with a high degree of precision in thermal uniformity. Because of the large thermal mass of the system, the ramp-up and ramp-down rates are severely limited. Another problem is that the relatively slow heat transfer results in a large time constant for the wafer to reach its equilibrium temperature. Thus furnace annealing is not very suitable for low–thermal-budget processing of semiconductors.

3.2.2 Rapid Thermal Annealing

Rapid thermal annealing (RTA) and pulsed laser annealing (PLA) both represent direct energy-transfer annealing methods. In both these methods optical energy is directly coupled with the semiconductor wafer, resulting in high ramp-up rates, thereby making them suitable for low–thermal-budget processing (Narayan *et al.,* 1985). Figure 11(a) shows a schematic diagram of a commercial RTA system manufactured by AG Associates. A bank of tungsten halogen lamps emitting incoherent radiation heats up a semiconductor wafer sitting in the chamber on quartz pins. The wavelength spread of this radiation is

FIG. 11. Schematic of (a) rapid thermal processing system and (b) a typical RTA thermal cycle.

very broad, extending from the ultraviolet to the infrared regions. The peak of the wavelength depends on the operating temperature of the lamp (3000–3600 K). The electromagnetic radiation from the lamps is directly coupled with the silicon wafer, which heats up rapidly. It should be noted that the silicon at low temperatures (<600 °C) is transparent to the infrared component of the radiation. However, at higher temperatures the wafer becomes completely absorbing to the incident radiation. The chamber and the wafer surroundings are nonabsorbing to the lamp radiation. Thus the thermal mass of a RTA system is much smaller than that of a typical furnace annealing system.

A typical processing temperature profile of a RTA process is shown in Fig. 11(b). The wafer is rapidly heated (50–200 °C/s) to temperatures in the range of 900–1200 °C, kept under steady-state condition for several seconds, and then ramped-down back to room temperature. Although the RTA system can process materials in the order of 10 s, there are two critical system issues that have still prevented its widespread use in the semiconductor industry. These issues are related to

1. noncontact techniques to measure temperature and
2. temperature uniformity on the wafer.

Pyrometric techniques have been developed to measure the temperature; however, the presence of other radiation and other effects (dopants, surface roughness) can affect the accuracy of the pyrometer significantly. Presently, new methods such as ripple pyrometry and temperature-independent pyrometry are being developed to address some of these issues.

Another critical issue in RTA equipment is the temperature uniformity across the wafer. To ensure that no defects are generated by thermal stresses, and to achieve a high process yield, the temperature across the wafer should be very uniform (±5 °C) for all stages of the thermal cycle (ramp-up, steady state, and ramp-down). The temperature nonuniformities are primarily introduced by higher radiative losses at the wafer edges compared to its center. To achieve thermal uniformity the bank of the lamps is divided into several zones, each of which is controlled independently. The power to each zone is adjusted by a closed-loop system so that the wafer can be uniformly heated. In addition, slip-free rings are placed at the wafer edges so that thermal radiation from the edges can be considerably reduced. It should be noted that despite the sophisticated temperature control systems, the maintenance of thermal uniformity is still one of the outstanding critical issues in RTA systems.

3.2.3 Pulsed Laser Annealing Pulsed lasers have also been extensively applied in research for annealing of semiconductors. Typically in this method the laser-induced rapid heating causes melting of the surface with the propagation of the melt interface into the solid, followed by resolidification of the melt region. Because the pulse durations are extremely short, the thermal effects are over in less than a microsecond. Various types of lasers have been employed by researchers for laser annealing experiments. The wavelengths of the lasers range from far infrared (wavelength $\lambda = 10.6\ \mu m$) to deep ultraviolet ($\lambda = 193$–308 nm). In the mid-1980s most solid-state lasers such as ruby ($\lambda = 694$ nm) and frequency-doubled YAG ($\lambda = 532$ nm) were extensively used for the laser annealing process. However, the solid-state laser has certain limitations for high-throughout processing of large-area devices. Foremost among these limitations are spatial homogeneity, small processing area, and low pulse-repetition rates. In addition, the absorption depth of the infrared laser beam is quite large and strongly temperature dependent, which may lead to nonlinear effects. Finally, the high coherency of these lasers results in spatial nonuniformities due to diffraction effects.

In the last ten years, a new class of laser called excimer lasers has been used extensively for materials processing. A mixture of rare-gas halide excited dimers (ArF, XeF, and KrF) acts as an active lasing medium. These excited dimers are formed during electrical excitation of the gas mixture. Because of strong absorption of radiation in the ultraviolet (UV) range by most semiconductors, the UV wavelength of the excimer laser results in high coupling of the laser beam with a variety of semiconductors. In addition, recent advances in laser technology have made available large-area laser beam sources, which can be used for annealing. Excimer lasers also are characterized by low coherency, thus eliminating the diffraction-related spatial nonhomogeneity effects. It should be noted that despite tremendous advances in excimer laser technology, full-wafer single-shot processing is still not practical.

The mechanisms for removal of microstructural damage by laser annealing are based on surface melting and resolidification. Figure 12 shows TEM micrographs of the excimer-annealed regions of boron-implanted silicon. Each micrograph corresponds to a different laser intensity irradiation on the implanted surface. The implanted specimens contain a high concentration of defects up to a depth of 0.7 μm. As shown in the figure, the thickness of the annealed regions varies linearly with energy density. Laser irradiation of ion-implanted samples leads to the removal of implantation damage up to the maximum melt depth. A complete removal of the dislocation loops in the annealed regions together with the sharp transition between the annealed and the unannealed regions is consistent with the first-order melting transition. The V-shaped dislocations containing stacking faults are created because the melt front intersects the dislocation loops, and the two segments for the dislocation grow back to the surface because the dislocation cannot be terminated within a perfect lattice.

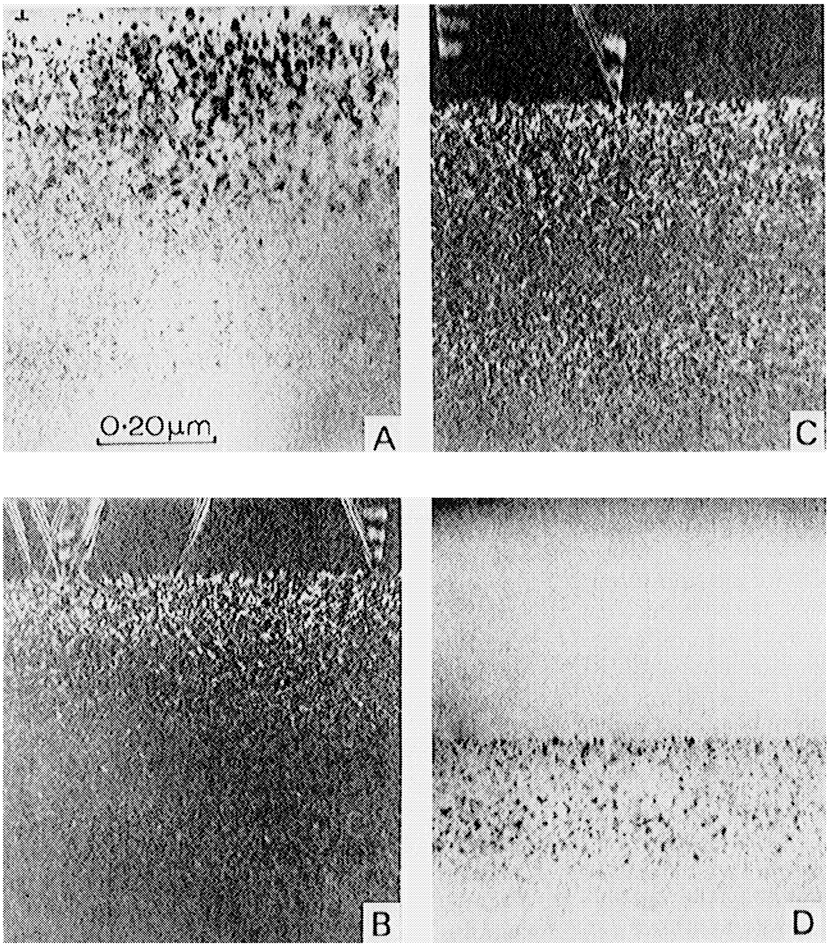

FIG. 12. TEM micrograph showing the depth of annealing or melting as a function of pulse energy density for 25- and 70-ns excimer laser pulses: (A) 1.0, (B) 1.5 J cm^{-2} (70 ns), (C) 1.0, and (D) 2.0 J cm^{-2} (25 ns). (Adapted from Singh and Narayan, 1989.)

The thickness of the melt region and the solidification velocities are controlled by the laser fluence and the pulse duration (Narayan and Holland, 1984). Figure 13 shows the position of the melt front with time for different pulse durations. From the curves it can be seen that the surface starts to melt slowly because of the sudden change in reflectivity of the materials. After the termination of the laser pulse, the melt front starts to recede back to the surface. At the initial stages of solidification, the solidification velocities are low but quickly reach a maximum when the steady-state curves are attained. The figure shows that as the pulse duration is increased, the maximum melt depth decreases accompanied with a concomitant decrease in the solidification velocity. From the slope of the solidification curves, the solidification velocities have been determined to be between 1 and 5 m/s.

Energy-balance considerations can be used to estimate the maximum melt depth during laser annealing of semiconductors (Singh and Narayan, 1989; Singh *et al.*, 1996). To determine the melt characteristics of the laser-irradiated materials, a threshold energy term E_{th} is defined, which corresponds to the energy that is lost by the solid part of the material undergoing laser irradi-

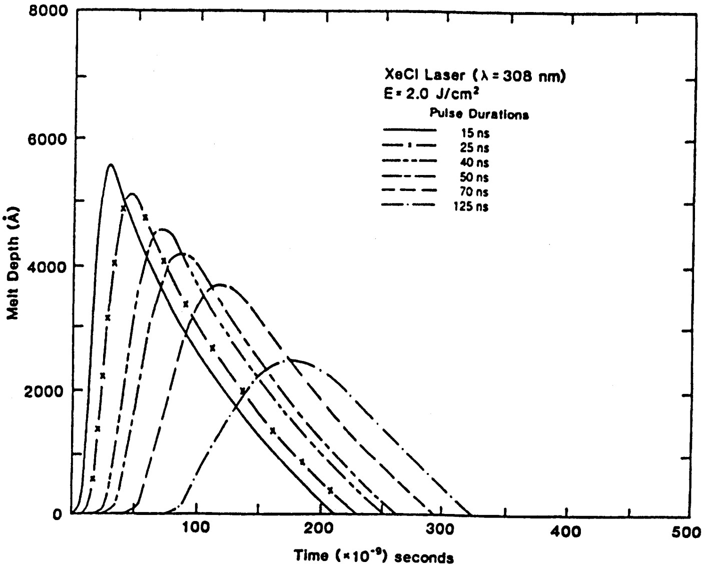

FIG. 13. Melt depth as a function of time for a 2.0-J-cm^{-2} excimer laser pulse irradiated on silicon for different pulse durations. (Adapted from Singh and Narayan, 1989.)

ation. Using energy balance considerations, the maximum melt depth, Δx, has been estimated to be

$$\Delta x = \frac{(1 - R_1)(E - E_{\text{th}})}{C_v T_m + L}. \tag{4}$$

The maximum melt depth, Δx, is plotted against incident fluence in Fig. 14. This figure shows a nearly linear relationship between the maximum melt depth and the incident fluence of the laser. Experimentally determined melt depths for various incident fluences are also shown in the same figure for comparison.

3.3 Technology Trends in Specialized Annealing Methods

Furnace annealing to remove defects has been extensively used on an industrial scale since the development of VLSI technology. However, the reduction in device dimensions has been the principal driver for more advanced annealing techniques in semiconductor processing. In order to reduce device dimensions and maintain suitable electrical characteristics of devices, the vertical dimension of the device must be reduced along with the lateral dimensions. The reduction in lateral dimensions is normally achieved by lithography, while the reduction in vertical dimensions required the ability to form ultrashallow *p-n* junctions. It is expected that for the future of 0.15-μm devices the junction depths will be as shallow as 300 Å. Therefore, annealing techniques are required that not only can activate dopants like boron but also can ensure that the dopant diffusion is minimized. Nonequilibrium techniques such as rapid thermal annealing and laser annealing have been developed so that the microstructural damage due to dopant implantation can be removed while at the same time ensuring that the diffusion profiles are not significantly affected by the thermal anneals.

4. THERMAL ANNEALING OF OXIDE MATERIALS

4.1 High-Temperature Superconductors

High-temperature superconductors are copper-oxide–based compounds that were first discovered by Bednorz and Müller (1986). The structures of the copper oxide–based superconductors are in general classified in terms of well-known structural types. For example, the structure of $YBa_2Cu_3O_7$, which superconducts at 90 K, is related to that of perovskite with apical oxygen atoms removed from the structure, while the arrangement of Ba- or Sr-doped La_2CuO_4 is identical to that of K_2NiF_4. The superconductors belonging to the system $Bi_2Sr_2Ca_2Cu_3O_{10}$ (T_c = 110 K) and $Tl_2Ba_2Ca_2Cu_3O_{10}$ (T_c = 123 K) have been compared to Aurivillius phases. Synthesis of these materials can be straightforward since they have been prepared successfully from mixed oxides using standard solid-state reaction. However, in order to obtain optimum desirable properties, e.g., high density, high fraction of superconducting phase, sharper transition temperature, and high current density, an understanding of various processing parameters, including sintering and annealing conditions, is essential. After sintering of the mixture of constituent oxides to a dense body typically in the range 900–975 °C, cooling rate and annealing environment must be carefully controlled, since these factors have been shown to exercise important influences on structure and superconducting properties. A brief discussion on the effects of annealing on each class of high-T_c superconductors follows.

$YBa_2Cu_3O_{7-x}$ (YBCO) is probably the most important system among high-temperature superconductors because its single-phasic preparation is relatively easy and does not involve any poisonous or hazardous components. It was the first superconducting material that was found to show superconductivity above liquid-nitrogen temperature. The YBCO system in bulk form is prepared by sintering a homogenous and stoichiometric mixture of Y_2O_3, BaO or $BaCO_3$, and CuO at 900–950 °C. The sintered powder is pelletized and annealed in oxygen ambient to obtain a sample with good superconducting and structural properties. The annealing conditions have been proved to have a profound effect on the superconducting and structural properties of these materials (Shyu *et al.*, 1988). Shown in Fig. 15 are the plots of normalized resistance vs temperature for five YBCO bulk samples obtained by annealing them in O_2 at different temperatures and different times. As seen in the figure the sample annealed at 950 °C for 4 h has the highest T_c and the narrowest transition. Higher temperature and longer times raise T_c, but 930–950 °C is required for a sharp transition. This should be expected because above approximately 900 °C the composition becomes partially molten, allowing grain growth, densification, and sintering to occur more rapidly. To increase the oxygen content, the YBCO samples are further annealed at 400–500 °C for several hours (5 to 10 h) in oxygen ambient. The annealing procedure for YBCO films on different substrates differs from the procedure used for annealing bulk YBCO samples in terms of dwell time at high temperature. The high-temperature (920–930 °C) step in the processing of YBCO films is extremely short, 3 min at the maximum. Despite the high temperature needed to achieve desired orientation, the short processing time is more important to preclude significant interaction of the film with the substrate.

Studies by various researchers have shown that the phases of Bi-Sr-Ca-Cu-O films are strongly affected by the annealing

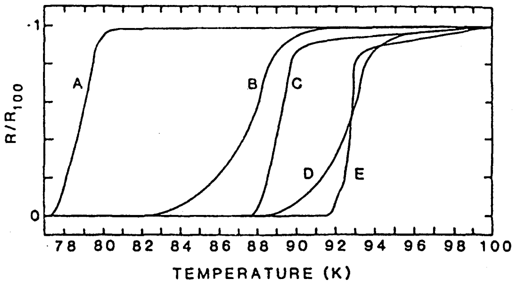

FIG. 15. Superconducting transitions for samples heat treated at (curve A) 890 °C, 30 min, (curve B) 910 °C, 4 h, (curve C) 930 °C, 4 h, (curve D) 910 °C, 23 h, and (curve E) 950 °C, 4 h.

temperature, time, ambient, and initial phases of the film. The annealing experiments show that the bismuth cuprate films melt at 865 °C in N_2, 875 °C in air, and 900 °C in oxygen. It has been observed that just melting the film is essential to obtain superconduction and for good adherence to the substrate. Table 2 shows the annealing conditions and conduction properties of Bi-Sr-Ca-Cu-O film on alumina substrates. The results presented in the table indicate that annealing at a low temperature is possible in nitrogen ambient. Since a complete annealing cycle in N_2 or O_2 does not produce superconduction in the film, a strategy of exposing the films in N_2 for a short time followed by air or air-oxygen flow in the furnace is employed. The advantages of adopting the N_2-air or N_2–air-O_2 sequence is that the film melts at a low temperature in nitrogen and subsequently solidifies at the same temperature when air or oxygen is introduced in the furnace. The film material absorbs the requisite amount of oxygen for superconduction when exposed to air or O_2 after melting in N_2. Thus the sequence of N_2–air-O_2 or N_2-air provides a kind of autocooling and perhaps is responsible for formation of the superconducting phase during regrowth of the melted film.

The preparation of thin films of Tl-based high-temperature superconductors is an important step to their potential applications in several devices. However, the fabrication of

Table 2. Annealing conditions and conduction properties of Bi-Sr-Ca-Cu-O films on alumina substrate.

Annealing conditions (temperature in °C)	Conduction property	T_c(K) $R = 0$

Tl-based superconducting films is very complicated because of the difficulty in maintaining proper stoichiometry, which arises from the volatile behavior of elemental Tl and its oxide compounds. One of the standard solutions is to deposit the stoichiometric films first at lower temperatures and then anneal the films at higher temperatures. The annealing at higher temperature is very crucial as the proper structure is realized during this step, not during the deposition at lower temperature. However, the low-temperature step provides the film with adequate adhesion and also influences the characteristics of subsequent annealing at high temperatures. Films deposited at higher temperatures tend to require a lower annealing temperature to achieve the highest T_c. Lee *et al.* (1989) obtained the Tl-based superconducting films with the highest T_c by annealing films deposited at ambient temperature and at 400, 895, and 805 °C for 1 h respectively. The highest T_c achieved tends to decrease with the increasing substrate temperature. For example, the highest T_c's observed were 121, 110, 103, 97, and 91 K for films deposited at ambient temperature and 200, 300, 400, and 500 °C, respectively. The four-point resistivity-versus-temperature data for the films deposited at ambient temperature and three at 300 °C, both post-annealed at 895 °C for 1 h, and for the film deposited at 400 °C and annealed at 805 °C for 1 h are shown in Fig. 16. Since these films have approximately the same starting composition before annealing, the different T_c's observed after annealing are likely related to microstructure-induced preferential growth of different superconducting phases during annealing. The lower-temperature annealing required for the films deposited at higher substrate temperatures is attributed to the film microstructure, which is more prone to material transport during annealing.

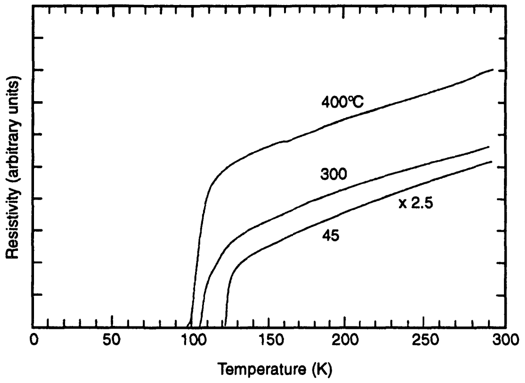

FIG. 16. Resistivity vs temperature for $Tl_2Ca_2Ba_2Cu_3O_{10}$ films sputter-deposited at ambient temperature and 300 °C both post-annealed at 895 °C for 1 h, and for the film deposited at 400 °C and annealed at 805 °C for 1 h.

4.2 Colossal-Magnetoresistive Materials

Magnetoresistance (MR), or the change in electrical resistance of a material in response to magnetic field, has a wide range of applications in digital information storage and retrieval. The MR phenomenon is the consequence of the ability of magnetic fields to change and thereby control the scattering of conduction electrons in metals so that the flow of electrical charge can be varied readily. The recent observation of colossal magnetoresistance (CMR) (up to 10^8 %) in perovskite lanthanum manganites $La_{1-x}M_xMnO_y$ (M = Ba, Ca, Sr) at high temperatures has generated further interest in the field (Jin *et al.*, 1994; Kumar *et al.*, 1996; Manoharan *et al.*, 1995). These CMR materials are both of technological interest due to their potential application as sensor materials and of scientific interest since the CMR mechanism is not yet fully understood, although explanations involving magnetic polaron scattering, double exchange, and metal–insulator transitions have been proposed. The MR ratio has been found to be strongly dependent on the microstructure of the oxide ceramic and the nature and amount of dopants in the lattice.

The CMR effect is more pronounced in epitaxial thin films and single-crystal materials. According to the literature, high-temperature post-annealing of CMR samples in oxygen or nitrogen ambient has been found to be beneficial in obtaining high CMR values. The post-annealing is critical in order to obtain high-quality films as this process raises metal–insulator transition temperature (T_c), drops resistivity by two or three orders of magnitude, and sharpens the magnetic signature of the ferromagnetic transition.

Shown in Fig. 17 are plots of MR ratio vs temperature for as-deposited and annealed $La_{0.6}Y_{0.07}Ca_{0.33}MnO_x$ (LYCMO) films. The as-deposited films were grown using pulsed la-

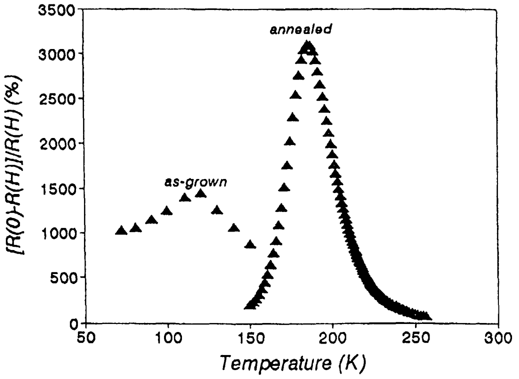

FIG. 17. The temperature dependence of MR ratio for as-deposited and 900 °C annealed films.

ser deposition (PLD) techniques in 300 mTorr of oxygen partial pressure and 650 °C substrate temperature. The same film, after the initial transport and magnetoresistance measurements, was annealed in oxygen for half an hour at 900 °C and characterized once again to see the effect of annealing. It is clear from this figure that a post-anneal process not only increases the metal–insulator transition temperature but also improves the MR ratio from 1500 to 3200%. Rutherford backscattering measurements indicate that the annealing process increases the oxygenation by 1–3%, whereas scanning tunneling microscopy (STM) and atomic force microscopy (AFM) reveal that the annealing process produces a tenfold increase in grain size. The improvement in the oxygenation process during post-annealing causes an increase in Mn^{4+}/Mn^{3+} ratio in the LYCMO films, which results in the realization of higher MR ratio at higher temperature. The enhancement in the grain size caused by the post-anneal process results in a decrease in the number of grain boundaries over a specified area. The grain growth is very important as it decreases the density of grain boundaries, which is responsible for the reduction in film resistivity. Therefore, annealing seems to be very important and advantageous for the realization of larger MR ratios at higher temperatures in CMR systems.

4.3 Ceramic Oxides

In ceramic oxides, such as the alkaline-earth oxide series (MgO, CaO, SrO, and BaO) and Al_2O_3, irradiation with energetic particles, such as neutrons, electrons, and ions, can produce lattice defects in the form of interstitials and vacancies in both the anion and cation sublattices. Annealing a ceramic oxide would generally return it to its initial virgin state except for vacancy mobility (Abraham *et al.*, 1976; Lee and Crawford, 1979; Halliburton *et al.*, 1973). The mobility of the interstitials and vacancies can be distinguished by performing experiments on two different types of crystals: those subjected to thermochemical reduction and those irradiated with energetic particles. Thermochemically reduced (TCR) crystals provide the means to determine vacancy mobilities, because they do not contain interstitials. They are prepared by heating the host crystals in a highly reducing atmosphere, such that oxygen ions in the crystal suffer stoichiometric deficiency, resulting in oxygen vacancies. The processing requirements can be stringent. For example, TCR of MgO crystals is performed at ~2000 K at ~7 atmospheres of magnesium vapor. The result of TCR is oxygen vacancies without oxygen interstitials. Thermal annealing experiments, monitored by optical absorption or EPR measurements, permit determination of the temperature at which these vacancies become mobile. In general, anion vacancies in ceramic oxides are mobile at temperatures in excess of 1400 K.

In the anion sublattice, stable anion interstitials and vacancies are produced. The anion vacancies annihilate at temperatures not much above room temperature. In MgO, CaO, and Al_2O_3, the temperatures at which anion vacancies begin to anneal are typically in the range of 400–600 K, well below the temperatures at which anion vacancies are known to be mobile (Lee and Crawford, 1977). Anion interstitials become mobile and recombine with the much more stable vacancies at these temperatures.

In simple oxides, such as MgO, CaO, and SrO, aliovalent impurities are always present. For example, MgO has the cubic rock-salt structure, and some of the defects can be represented in the following linear configurations (Lacy *et al.*, 1978; Unruh *et al.*, 1973):

$Mg^{2+}O^{2-}[Mg^{2+}$ vacancy$]O^{-}Mg^{2+}$,
V^{-} center, $E_A = 1.6$ eV;

$Al^{3+}O^{2-}[Mg^{2+}$ vacancy$]O^{-}Mg^{2+}$,
V_{Al} center, $E_A = 1.13$ eV;

$Mg^{2+}OH^{-}[Mg^{2+}$ vacancy$]O^{-}Mg^{2+}$,
V_{OH} center, $E_A = 0.84$ eV;

$Mg^{2+}O^{2-}Li^{+}O^{-}Mg^{2+}$, $[Li]^0$ center,
$E_A = 0.6$ eV,

where O^- represents a hole trapped at an O^{2-} ion site. The source of the holes can be from any ionizing radiation, such as electron irradiation, x rays, or gamma rays; these radiations create electron–hole pairs. Whereas the electrons are trapped by transition-metal impurities such as Fe ions, the holes are trapped at the V centers. The lithium impurity is not normally present in MgO crystals but can readily be doped in.

The holes are metastable at room temperature, varying from half-lives of order seconds in the $[Li]^0$ center, to a few hours in the V_{OH} and V_{Al} centers, to a few years in V^- centers. Given the different structures of the trapped-hole centers illustrated above, one would intuitively expect that the rate at which a hole thermally ionizes from a specific V center increases with the proximity of the O^- ion to the excess positive charge of the impurity. For example, the O^--to-H^+ distance is smaller than the O^--to-Al^{3+} distance. Therefore the stability of the hole should be less for the V_{OH} center. For the $[Li]^0$ center, the O^- ion is right next to the Li^+ ion, and the hole should be the least stable. Hence one would expect the order of increasing stability to be $[Li]^0$, V_{OH}, V_{Al}, and V^- centers. Indeed, this appears to be the case. The V^- center can also be regarded as a cation vacancy whose impurity charge compensator is at infinity.

The annealing of ceramic oxides may lead to recombination of anion vacancies and their subsequent migration to the grain boundaries or surfaces. The annealing may also cause recombination of interstitials with vacancies. While the former type of recombination is marked by a small increase in light scattering in the crystal, the latter type is marked by loss of displacement damage by the irradiating particles. Sometimes, the annealing may also bring about the release of holes from V-type centers, the holes recombining with electrons trapped earlier at the impurity sites such as Fe ions. The half-lives of the holes released are reflected in terms of experimentally obtained activation energies E_A showing a monotonic trend as mentioned above.

5. CONCLUSIONS

A brief review of the salient characteristics of furnace, rapid thermal, and laser annealing techniques is presented along with discussions focused on the roles they play during annealing of metals, semiconductors, and ceramic oxides. The annealing process consists of three stages, which involve heating the workpiece to the desired temperature, holding or soaking at that temperature, and cooling back to room temperature. The annealing treatment is primarily conducted to alter and produce specific microstructure. At elevated temperature, the defects or imperfections in solid materials, such as vacancies, interstitials, and dislocations, become mobile and thus can be tailored for specific requirements.

In metallic alloys, thermal annealing is carried out to relieve stresses, increase softness, ductility, and toughness, and/or produce a specific microstructure. A variety of annealing heat treatments in metals are possible, which are characterized by the changes that are induced. These changes are mostly related to microstructure, resulting in the alteration of the mechanical properties of metals or metal alloys. Annealing has been shown to play a critical role in semiconductors in the fabrication of very large-scale integrated (VLSI) circuits. The drive toward lower cost and larger-scale integration in electronic circuits has placed increasing demands on the development of annealing techniques that can remove the defects without significant diffusion of dopants. This has led to the development of newer thermal annealing techniques such as rapid thermal annealing (RTA) and pulsed laser annealing (PLA). Thermal annealing is also very useful for optimizing the desirable properties of high-temperature superconducting (HTS) and colossal magnetoresistive (CMR) oxide materials. It has been shown that annealing of bulk as well as thin-film high-temperature superconductors results in the realization of high density and high fraction of superconducting phase, sharper transition temperature, and high current density. The post-deposition annealing of colossal magnetoresistive films is also very critical in order to obtain high-quality films, as this process raises the metal–insulator transition temperature, drops resistivity drastically, and sharpens the magnetic signature of the ferromagnetic transition. Annealing of ceramic oxides has been found useful in the removal of lattice defects caused by irradiation with energetic particles and thereby returning the oxide lattice to its initial virgin state except for the vacancy mobility.

GLOSSARY

Austenites: Iron and steel alloys that have face-centered-cubic crystal structure.

Bainite: An austenitic transformation product found in some steels and cast irons.

Cold Working: The plastic deformation of a metal at temperature below that at which it recrystallizes.

Eutectoid Reaction: A reaction wherein, upon cooling, one solid phase transforms isothermally and reversibly into two new solid phases that are intimately mixed.

Martensite: A metastable iron phase supersaturated in carbon that is the product of a diffusionless transformation from austenite.

Pearlite: A two-phase microstructure found in some steels and cast irons that results from the transformation of austenite of eutectoid composition.

Shear: A force applied so as to cause or tend to cause two adjacent parts of the same body to slide relative to each other, in a direction parallel to their plane of contact.

INTRODUCTION

The transfer of heat from one point in a medium to another is an example of flow taking place under the influence of a "driving force," which in this case is a temperature gradient. Other transport properties will inevitably enter any treatment of thermal conduction in metallic liquids, the most important being the electrical conductivity. In this case the force is provided by the gradient of the electrical potential. We shall see below, from both theory and experiment, that there is an intimate relation between thermal conductivity λ and electrical conductivity σ, in metallic liquids such as molten Cu or Na. A third transport process that is invoked later on in this article is diffusion, the "driving force" this time being a concentration gradient.

Quantitative studies of these processes have a long history, and in particular in the case of thermal conduction, the flow of heat was shown by Fourier (1822) to be a linear function of the temperature gradient driving the flow. Ohm and Fick established analogous linear relations for electricity and for mass transport, respectively. Thus one writes a so-called phenomenological linear relationship for one dimension, x, say, as

$$J_q = -\lambda \frac{dT}{dx}, \tag{1}$$

where J_q is the heat flow per unit area per unit time, T is the temperature, and λ is the coefficient of thermal conductivity. We turn immediately to summarize the essence of one direct method of measuring the thermal conductivity.

1. DIRECT MEASUREMENT

When a temperature gradient is applied to a liquid, heat transfer may take place by one or more of the following mechanisms:

1. pure heat conduction,
2. convection, which is the transfer of relatively large masses of liquid from the cold to the hot zone, or
3. radiation.

In practical setups, contribution **3** is normally small in comparison with the others and can usually be ignored. Heat transfer by convection may be comparable with, or larger than, heat transfer by conduction, and it is essential to minimize it in any determination of the thermal conductivity of liquid metals.

The experimental method used by Goldratt and Greenfield (1980) consists in measuring the temperature profile along a sample enclosed in a thin-walled stainless steel tube, which was coated with a high-emissivity paint and was *in vacuo*. The sample, enclosed within a constant-temperature environment, was heated from above and allowed to radiate freely. In the steady state, the radiation to the surrounding constant-temperature enclosure leads to a temperature gradient along the sample. The resulting temperature profile of the sample can then be measured with an infrared microscope traveling inside the vacuum along the length of the sample.

From this measured temperature profile, Goldratt and Greenfield (1978) set out a straightforward procedure to obtain the thermal conductivity $\lambda(T)$ as a function of temperature throughout the extent of the measured temperature profile. As these workers stress, this procedure provides the value of λ for each sample at its temperature T. In particular, they emphasize that they do not determine an average of $\lambda(T)$ over a range of temperature, nor need it be assumed that the temperature gradient is linear.

An important feature of the above method is that it allows an independent check to be made of the results, making possible the detection of systematic errors. By resetting the heater, one finds a different steady-state temperature profile, for which the temperature gradient at each temperature is different from that of the previous heater setting. Furthermore, any given temperature occurs at different locations along the sample for each of the two heater settings. It follows that accord between the two measurements of $\lambda(T)$, calculated from the two different heater settings, greatly reduces the possibility of systematic errors. As an example of the use of this technique, the results of Goldratt and Greenfield (1980) for liquid metal In are reported below, as an illustration of the effect of the freezing transition on especially the Lorenz number of this liquid metal.

In their particular experiment, the indium metal was 99.999% pure. Sample tubes, of 2 cm diameter and 15 cm length, were filled with molten indium and slowly cooled from below to prevent the formation of bubbles. Experimental checks were performed to ensure sample homogeneity as well as the absence of convection in the liquid.

Above, it has been pointed out that convection is a troublesome aspect in relation to direct measurement of thermal conductivity. This may be the reason why, in Cubbery (1979), if one selects liquid Ga, say, one finds a considerable spread of values at 350 K, the melting point of Ga being 302.9 K. The extremes of three values recorded have a ratio of 1.25. Because of this spread, λ has been measured directly by Okada and Ozoe (1992) in a convection enclosure. They remark that the measurement of thermal conductivity should be carried out for a shallow fluid layer. Their finding is that the thermal conductivity of Ga can be fitted by

$$\lambda_{\mathrm{Ga}} = -7.45 + 0.1256T \quad \mathrm{W/(m \cdot K)} \tag{2}$$

for $306\ \mathrm{K} \leq T \leq 312\ \mathrm{K}$. The errors $\delta\lambda$ decrease as the temperature is raised, from ±2.6 at 307.7 K to ±0.9 at 312.1 K.

2. RELATION TO ELECTRICAL CONDUCTIVITY

The electrical conductivity, loosely speaking, is a measure of the ease with which charge can be carried through the liquid metal, whereas with thermal conduction we are concerned, of course, with the transfer of thermal energy.

It turns out that one can adapt the classical kinetic theory of the heat conductivity of gases, as set out, for example, in the book by

Jeans (1940), for the present purposes. Taking this formula quite literally for a moment, one can write

$$\lambda = \tfrac{1}{3} c_v v l, \tag{3}$$

where c_v is the specific heat per unit volume, v is the appropriately averaged velocity, while l is the mean free path of the gaseous molecules.

Turning to the electrons in liquid metals, even at the melting temperature T_m the thermal energy $k_B T_m$, k_B being Boltzmann's constant, is only a small fraction of the Fermi energy E_F, which is typically some electron volts in simple metals. Thus, the specific heat per electron in the Fermi gas, which the conduction electrons in a simple liquid metal near freezing constitute, is the classical value got from the equipartition of energy, namely $(\frac{3}{2})k_B$ multiplied by the fraction of electrons near the Fermi surface, which is evidently of the order of $k_B T/E_F$. Therefore, with electron density denoted by n, the specific heat in Eq. (3) can be taken to be approximately $3nk_B^2T/2E_F$. The factors can be calculated exactly for a free-electron-gas model (see, for example, Ziman, 1960), with the result for the electronic specific heat c_{el}

$$c_{el} = \pi^2 n k_B^2 T / 2E_F. \tag{4}$$

The velocity v in the kinetic formula, by arguments essentially the same as above, can be replaced by the Fermi velocity v_F:

$$m v_F^2/2 = E_F. \tag{5}$$

Hence the electronic contribution to the thermal conductivity of the liquid metal can be written

$$\lambda_{el} = \pi^2 n k_B^2 T l / 3 m v_F. \tag{6}$$

But the relaxation time τ (see below for more detail) is in this case of degenerate electrons given by the simple formula

$$l = v_F \tau, \tag{7}$$

and hence one is led to the result

$$\lambda_{el} = \pi^2 n k_B^2 T \tau / 3m. \tag{8}$$

2.1 Role of Relaxation Time

Following the so-called Drude model, let us assume that an electron experiences a collision, resulting in an abrupt change in its velocity, with a probability per unit time that is written as $1/\tau$. This means that the probability of an electron undergoing a collision in any infinitesimal interval of time dt is dt/τ. The time τ is most frequently referred to as relaxation time, already used above, but some authors term it collision time or, occasionally, mean free time. This time τ plays a very basic role in the theory of electronic transport in metallic conductors such as molten metals under discussion here.

It then follows from the above that an electron selected at random at a chosen instant will, on average, travel for a time τ since its last collision. In the simplest form of the Drude model, the relaxation time τ is taken independent of the position or velocity of an electron. This turns out (compare Ashcroft and Mermin, 1976) to be a good assumption for many, though not for all, applications.

It is also assumed that electrons come to thermal equilibrium with their surroundings only through collisions. These collisions are taken to maintain local thermodynamic equilibrium in a very simple manner. Immediately after each collision, an electron is supposed to emerge with a velocity that is not related to its velocity immediately before the collision, but randomly directed. The time τ in a liquid metal is typically 10^{-14} to 10^{-15} s.

2.2 Current Density Related to Relaxation Time

Let us now introduce the current density $\mathbf{j}$. It is a vector parallel to the flow of charge, whose magnitude is the amount of charge per unit time crossing a unit area perpendicular to the flow.

At any point in a liquid metal, electrons, as mentioned above, are always moving in a variety of directions. If the number of electrons per unit volume is denoted by n, the electronic charge by $-e$, then if $\mathbf{v}$ is the average electronic velocity, the net current density is given by

$$\mathbf{j} = -ne\mathbf{v}. \tag{9}$$

Without the application of an electric field, electrons are just as likely to be moving in any one direction as in any other. Thus the velocity $\mathbf{v}$ will average to zero and there is no net flow of current. But when an electric field $\mathbf{F}$ is applied, there will be a mean electronic velocity directed in the opposite sense to the field, the electronic charge being negative.

The next step is to relate the velocity in the presence of the field $\mathbf{F}$ to the relaxation time τ. This can be achieved as follows. Let us focus on a typical electron at time $t = 0$. Let t be that time that has elapsed since it last experienced a collision. Its velocity at time $t = 0$ will be that, say $\mathbf{v}_0$, immediately after that collision, plus the added velocity $-e\mathbf{F}t/m$ it has acquired in the field $\mathbf{F}$ since that last collision. Since it is assumed that an electron emerges from a collision in a random direction, there will be no contribution from $\mathbf{v}_0$ to the average electronic velocity: This will only depend on the average of $-e\mathbf{F}t/m$. But the average of t is the relaxation time τ, and therefore one can write

$$\mathbf{v} = -e\mathbf{F}\tau/m, \tag{10}$$

and hence it follows from Eq. (9) that the current density $\mathbf{j}$ may be written in the form

$$\mathbf{j} = -(ne^2\tau/m)\mathbf{F}. \tag{11}$$

But the electrical conductivity σ is introduced through

$$\mathbf{j} = \sigma\mathbf{F}, \tag{12}$$

the electrical resistivity ρ being the reciprocal of σ. From Eqs. (11) and (12), one arrives at the basic formula for the electrical conductivity of a liquid metal, namely

$$\sigma = ne^2\tau/m. \tag{13}$$

2.3 Wiedemann–Franz Law: Relation between Thermal and Electrical Conductivity in a Metallic Conductor

Let us now combine Eq. (8) for the electronic contribution to the thermal conductivity of a liquid metal with Eq. (13) for the electrical conductivity. Then one can readily show that

$$\frac{\lambda_{\mathrm{el}}}{\sigma T} = \frac{\pi^2}{3}\left(\frac{k_{\mathrm{B}}}{e}\right)^2 = \text{const}, \tag{14}$$

where the constant, usually denoted by L, is called the Lorenz number and has a value of 2.45×10^{-8} W·Ω·K^2.

Before discussing the relation of the Wiedemann–Franz law (14) to experiment, we summarize below the way the ratio L involving the thermal conductivity of metals can be directly measured (see also the review by Powell, 1969).

3. KOHLRAUSCH METHOD OF MEASURING RATIO OF THERMAL TO ELECTRICAL CONDUCTIVITY

We began this account of thermal conduction with a direct measuring technique for liquid metals. But it is much simpler to measure the electrical conductivity of a liquid metal than the thermal conductivity. Hence, if the Wiedemann–Franz law were fully quantitative, it would enable the thermal conductivity to be got directly from the measurement of electrical conductivity, provided the electronic contribution dominated the total thermal conductivity. While this is most often the case, insulating liquids exhibit thermal conduction, as discussed at length in THERMAL CONDUCTIVITY OF NONMETALLIC LIQUIDS.

However, before we embark on the question of "deviations" from the Wiedemann–Franz law, we note that this relation between λ and σ has motivated measurements of the ratio directly, and to such an approach we now turn. The method goes back to Kohlrausch (1900, 1960) and has been utilized by Busch and co-workers (1972). The method was originally designed by Kohlrausch (1900) for measurements on solids. It has been employed specifically by Busch *et al.* (1972) to make measurements on both solid and liquid Ga, and also on both phases of Hg. Their approach and results form the basis for what follows.

Reference may be made to Fig. 1 to see the way in which Busch *et al.* extended the Kohlrausch method to liquids; the constriction-shaped sample depicted there schematically was used. Given the assumption that the Wiedemann–Franz law holds, the Lorenz number is given by

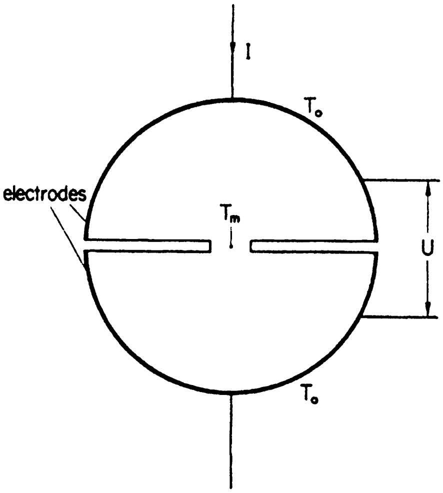

FIG. 1. Schematic representation of the constriction-shaped Ga sample used in extension of Kohlrausch method to liquid metals by Busch *et al.* (1972).

$$L = \tfrac{1}{4}\, U^2/(T_{cc}^2 - T_0^2). \qquad (15)$$

Here U is the voltage across the constriction, T_0 is the temperature, which is held constant, of the electrodes, while T_{cc} is the temperature in the center of the constriction. As already mentioned above, for the experiments on the liquid state using this technique, special attention needs to be paid to eliminate the influence of heat convection and other disturbing influences. Table 1 collects the data on the Lorenz number for solid and liquid Ga near the melting temperature $T_m = 303$ K. The material used was of high purity (99.999%), as obtained by Busch *et al.* (1972). These workers estimate that their experimental errors are less than 0.2%, and they find that their measurements show deviations from the theoretical value of the Lorenz number L in Eq. (14) of less than 1%. Subsequently, Busch *et al.* (1972) have made similar measurements to those just reported on Ga on solid and liquid mercury. These were made over the temperature range 225–350 K, the melting point being 234.8 K. Table 2 shows the measured Lorenz number L for these two phases of mercury, for the same purity as for Ga above. Busch *et al.* note that the experimental error in L is somewhat larger than for Ga for a variety of reasons.

To conclude this section, it is clear that for these two materials, the most accurate way at the time of writing to determine absolutely the thermal conductivity λ is via the Kohlrausch-type measurement of the Lorenz number, which is then to be combined with a direct measurement of the electrical conductivity σ. For the two materials Ga and Hg so far studied in this way, the theoretical estimate of the Lorenz number is verified to an accuracy of the order of the experimental error in the measurement of L. Nevertheless, there are theoretical principles that allow deviations from the theoretical estimate of the Lorenz number in Eq. (14), and we shall briefly summarize these in Sec. 7. Before leaving the topic of Lorenz number, we record that the nearly-free-electron (NFE) theory of electrical resistivity of liquid metals initiated by Krishnan and Bhatia (1945) and brought to full fruition by Ziman (1960) using pseudopotentials affords for simple *s-p* metals such as Na an almost quantitative route to calculate the electrical resistivity at the freezing point. However, it is known for the heavy alkali metals, Rb and Cs, that this theory will not work as liquid metals are taken up toward the critical point along the liquid–vapor coexistence curve (see, for example, Ascough *et al.*, 1988, for liquid metal Rb). This theory of electrical resistivity is posed in terms of the static liquid structure factor $S(q)$ and, as already mentioned, a suit-

Table 1. Lorenz number of solid and liquid Ga (near the melting point 303 K). After Busch *et al.* (1972).

Temp. (K)	L (V^2 deg^{-2})	Temp. (K)	L (V^2 deg^{-2})
293.3	2.447×10^{-8}	307.3	2.463×10^{-8}

242.4	2.424×10^{-8}	321.6	2.440×10^{-8}
273.0	2.467×10^{-8}	339.1	2.454×10^{-8}

able (screened) pseudopotential—see, for instance, Faber (1972), and also March (1990).

3.1 Effect of Liquid–Solid Freezing Transition on Conductivities Separately and on Lorenz Number: Example of In

Goldratt and Greenfield (1980) have obtained experimental data for thermal conductivity λ and Lorenz number L for metallic In on either side of the melting point. In Fig. 2 the thermal conductivity in the two phases is plotted, the vertical dashed line marking the melting point. Evidently, there is a very marked increase in the measured thermal conductivity as the liquid metal freezes, by something approaching a factor of 2. But as Fig. 3 demonstrates, there is a relatively mild variation only in the Lorenz number as one passes through the freezing point. The horizontal line in Fig. 3 shows the theoretical prediction of L in Eq. (14). To conclude this section, Table 3 records for a variety of liquid metals measured values of the Lorenz number L, compiled from Faber (1972).

4. NEUTRON SCATTERING AND DYNAMICAL STRUCTURE

So far, we have not discussed structural properties beyond reference to the static structure factor $S(q)$, which entered the NFE theory of electrical resistivity as one of the crucial ingredients (see Sec. 3). Since thermal conductivity is a transport property, it enters the equations of hydrodynamics for a liquid metal (see, for example, March, 1990), or a binary liquid-metal alloy, both of these systems being considered below. It is natural to begin with a pure liquid metal.

4.1 Influence of Thermal Conductivity on Dynamical Structure Factor

We focus below on the way that thermal conduction is reflected in the dynamical structure factor $S(q,\omega)$ of a liquid metal. The physical meaning of this quantity, introduced into the theory of metals by Van Hove (1954), is that it represents the probability that a neutron incident on the liquid will transfer momentum $\hbar q$ and energy $\hbar\omega$ to the liquid. One immediate property of $S(q,\omega)$ is that, when it is integrated over all energy transfers, the static structure factor $S(q)$ mentioned above is regained:

$$\int_{-\infty}^{\infty} S(q,\omega)d\omega = S(q). \tag{16}$$

The hydrodynamic equations have already been referred to. These, in suitable linearized form, are invoked below to set up the form of $S(q,\omega)$ in the appropriate regime in which the hydrodynamic equations have validity. These equations are, in fact, valid in the long-wavelength and low-frequency limits, or, equivalently, in the Fourier-transform

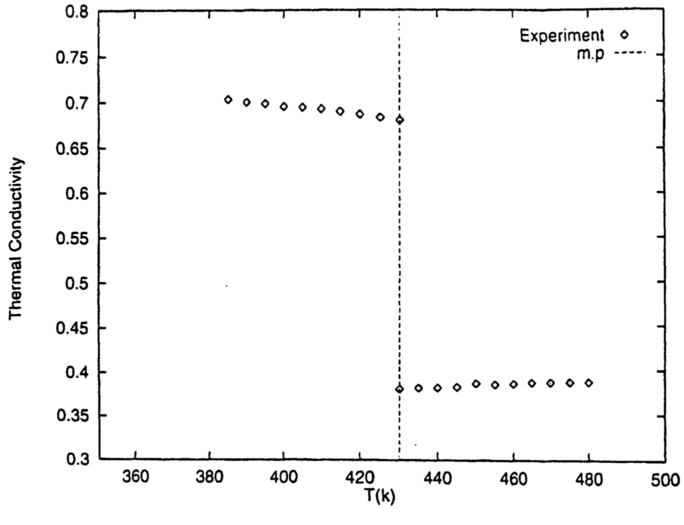

FIG. 2. Variation of thermal conductivity of indium with temperature as measured by Goldratt and Greenfield (1980).

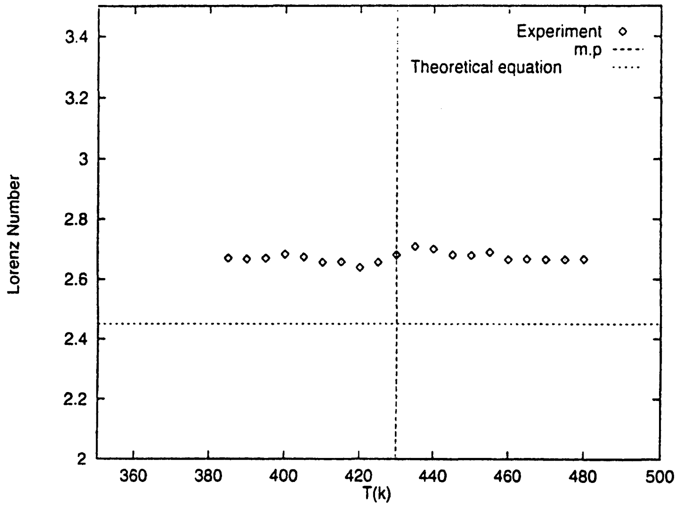

FIG. 3. Variation of Lorenz number of indium with temperature as measured by Goldratt and Greenfield (1980).

variables $\mathbf{q} \to \mathbf{r}$, $\omega \to t$, the limit of large r and long time t. Following the pioneering work of Landau and Placzek (1934), the usual procedure of such a calculation is to use the linearized hydrodynamic equations of irreversible thermodynamics to describe the relaxation in time of relevant fluctuating thermodynamic variables in the liquid; this procedure is reviewed, for example, by Mountain (1970).

Though more detail will be reported below for liquid-metal alloys, let us summarize here the main physical content emerging from such an approach. There are basically three peaks evident in $S(q,\omega)$ as a function of angular frequency ω. The central ($\omega = 0$) component (Rayleigh peak) is found to consist of the sum of two Lorentzians, the width of one of these being controlled largely by thermal conduction [compare Eq. (21) below]. There are then two "Doppler-shifted" peaks, referred to as Brillouin components, centered at frequencies $\omega = \pm C_0 q$ where C_0 is the adiabatic speed of sound given by

$$C_0 = \left(\frac{\partial P}{\partial \rho}\right)_S^{1/2}, \tag{17}$$

where S is the entropy. These peaks arise from sound propagation in opposite directions (for a given wave vector $\mathbf{q}$), and their width, having the form Γq^2, turns out to be controlled by acoustic attenuation (see also below). It is noteworthy that the ratio of the integrated intensity I_0 of the Rayleigh components in $S(q,\omega)$ to that of the doublet Brillouin side peaks, $2I_1$, is quite generally given by

$$I_0/2I_1 = \gamma - 1. \tag{18}$$

Table 3. Lorenz numbers $L \times 10^8$ in units of W Ω K^{-2} for a variety of liquid metals (Faber, 1972; see also Tankeshwar and March, 1996).

Metal	$L \times 10^8$	Metal	$L \times 10^8$	Metal	$L \times 10^8$
Li	2.6	Pb	2.4	Ta	2.4
Na	2.2	Sb	2.6	Re	1.75
K	2.1	Bi	2.5	Os	1.75
Cs	2.4	Ti	2.9	Pt	2.3
Cd	2.5	Zr	2.25	In	2.7
Hg	2.75	Hf	2.7	La	2.65
Zn	3.2	Mo	2.6	Ce	2.56
Al	2.4	W	2.5	Pr	2.89
Ga	2.07	Ru	2.45	Nd	2.27
Tl	3.2	Ir	1.95	Gd	1.83
Sn	2.9	Nb	2.6	Dy	2.34

The generalization of this result to liquid-metal alloys in which there are size differences between the two components is treated later.

There are also "non-Lorentzian" parts in $S(q,\omega)$, though these make no contribution to the integrated intensity and, usually, only a relatively small contribution to the intensity distribution. However, if $\Gamma q/C_0$ is not much less than unity, they can markedly affect the position and shape of the Brillouin peaks in $S(q,\omega)$.

5. BINARY LIQUID-METAL ALLOYS

Turning from pure metals to binary liquid alloys, we note first that Bhatia and Thornton (1970) introduced number–concentration (N-C) dynamical structure factors $S_{NN}(q,\omega)$, $S_{NC}(q,\omega)$, and $S_{CC}(q,\omega)$ to describe the structural aspects of scattering processes in such alloys.

5.1 Role of Thermal Conduction in Neutron Scattering

The aim in what follows is to discuss the hydrodynamic limit of long wavelength and low frequency of the N-C dynamical structure factors of such a liquid alloy. This follows the approach of Bhatia *et al.* (1974), who made extensive use of the earlier study of Cohen *et al.* (1971). These workers gave results for correlations between mass density and mass concentration. Let us first consider $S_{NN}(q,\omega)$. If we take the limit of a dilute alloy such that the concentration c goes to zero, then $S_{NN}(q,\omega)$ becomes the dynamical structure factor of pure liquid metal discussed above. Paralleling the discussion of $S(q,\omega)$, the Rayleigh component in $S_{NN}(q,\omega)$ is again found to consist generally of the sum of two Lorentzians. As before, the width of one Lorentzian is largely controlled by thermal conduction, the other by mutual diffusion. The two Doppler-shifted (Brillouin) components are largely as in the one-component case [see Bhatia *et al.* (1974) for fuller details of $S_{NN}(q,\omega)$ in the hydrodynamic regime]. It is worth noting that the formula for the ratio of the integrated intensity I_0 of the Rayleigh components in $S_{NN}(q,\omega)$ to that of the doublet Brillouin side peaks, $2I_1$, is modified from the result of Eq. (18). Though still proportional to $\gamma - 1$, with γ of course the specific heat ratio at the particular concentration considered in the liquid alloy, there is a multiplying factor of the form $1 + \text{const.} \times \delta^2$, where δ measures the size difference of the two components in the alloy:

$$\delta = \frac{1}{V}\left[\frac{\partial V}{\partial c}\right]_{P,T;N} = \frac{v_1 - v_2}{v}. \tag{19}$$

Here $v_\alpha = [\partial V/\partial N]_{P,T,N,\beta}(\beta \neq \alpha)$ denotes the partial molar volume, per atom, of species α, while v, the mean molar volume per atom, is given by

$$v = \left[\frac{\partial V}{\partial N}\right]_{P,T,c} = cv_1 + (1 - c)v_2. \tag{20}$$

Of course, in the dilute-alloy limit c tends to zero, whereas S_{NN} tends to the one-component $S(q,\omega)$, and S_{NC} and S_{CC} tend to zero. These two quantities are therefore crucially about the alloy at finite concentration c. Let us write out the essence of the form of S_{NC}, without going into full details (for these, see Bhatia *et al.*, 1974). It is such that

$$\begin{aligned} S_{NC}(q,\omega) = \frac{Nk_BT}{2\pi}\Bigg[&\frac{K_1q^2}{\omega^2 + X^2q^4} + \frac{K_2q^2}{\omega^2 + Y^2q^4} \\ &+ K_3\left(\frac{\omega + C_0q}{(\omega + C_0q)^2 + \Gamma^2q^4} - \frac{\omega - C_0q}{(\omega - C_0q)^2 + \Gamma^2q^4}\right)\Bigg]. \end{aligned} \tag{21}$$

In this general expression, the constants are all known in terms of macroscopic constants, both thermodynamic and irreversible transport coefficients being involved. The two Lorentzians (terms involving K_1 and K_2) primarily arise in the number–concentration structure factor $S_{NC}(q,\omega)$ respectively from diffusive processes and the coupling between this type of mode and the thermal conductive mode. If this coupling is zero, then the latter component is no longer present and the width of the remaining Lorentzian is simply Dq^2, where D is the coefficient of mutual diffusion.

The concentration–concentration structure factor is of the essence in understanding the thermodynamic properties of liquid binary alloys, when integrated over all energy transfers ω. As to its frequency dependence, this again follows from the linearized hydrodynamic equations and has the form of the sum of two Lorentzians:

$$S_{\mathrm{CC}} = \frac{Nk_{\mathrm{B}}T}{2\pi Z}\left[\frac{K_3q^2}{\omega^2 + X^2q^4} + \frac{K_4q^2}{\omega^2 + Y^2q^4}\right]. \tag{22}$$

These two components behave in a similar manner to the Lorentzians in $S_{\mathrm{NC}}(q,\omega)$. The quantity Z appearing in Eq. (22) is related to the Gibbs free energy G of the liquid alloy by

$$Z = \left(\frac{\partial^2 G}{\partial c^2}\right)_{P,T,N}. \tag{23}$$

5.2 Thermal Conduction in Relation to Ultrasonic Attenuation

The way in which thermal conduction affects sound-wave attenuation in liquid-metal alloys is considered here. Specifically, the width Γq^2 of the Brillouin components in the number–number dynamical structure factor $S_{\mathrm{NN}}(q,\omega)$ is related to the acoustic attenuation in the liquid. Explicitly, the amplitude attenuation per wavelength, α, is given by

$$\frac{\alpha}{\omega} = \frac{\pi[\zeta + (4/3)\eta]}{\rho C_0^2} + \frac{\pi(\gamma - 1)\lambda M}{\rho C_0^2 C_p} + \left[\frac{\alpha}{\omega}\right]_D, \tag{24}$$

where

$$\left[\frac{\alpha}{\omega}\right]_D = \frac{\pi MD}{Z}\left[\delta - \delta_m + \frac{Zk_T\alpha_T}{C_p}\right]^2. \tag{25}$$

The first two terms appearing in Eq. (24) come from

1. bulk (ζ) and shear (η) viscosities, and
2. attenuation caused by thermal conductivity, our main interest here,

while the last term gives the contribution due to diffusion. Bhatia *et al.* (1974) consider the limiting case of Eqs. (24) and (25) for an ideal-gas mixture. Here there is no size effect, so $\delta = 0$, the coefficient of thermal expansion $\alpha_T = 1/T$, while the isothermal compressibility $K_T = 1/P$, as follows from the ideal-gas equation of state $PV = Nk_{\mathrm{B}}T$. From the Gibbs free energy in this ideal-gas model, it is readily shown that Z is given by

$$Z = Nk_{\mathrm{B}}T/c(1 - c). \tag{26}$$

Hence, for the last term one readily finds

$$\left[\frac{\alpha}{\omega}\right]_D = \pi Dc(1 - c)\frac{\rho}{P}\left[\frac{m_2 - m_1}{m} + \frac{(\gamma - 1)\beta}{\gamma}\right]^2, \tag{27}$$

where $\beta = k_T/c(1 - c)$, the thermal diffusion factor, has been introduced. This formula has been derived previously from kinetic theory calculations and has been verified experimentally for noble-gas mixtures of various compositions. For a fuller discussion of ultrasonic absorption, and in particular the role of thermal conduction, the reader may consult the book by Bhatia (1967).

6. TECHNOLOGY OF LIQUID METALS AND ALLOYS

Some of the motivation for much research on liquid metals and their alloys has come directly from the standpoint of practical engineering utility. This is discussed at length in the book by Sittig (1956), with the focus on sodium and its alloys in the liquid phase. It is worth noting, because of the very important role of sodium, the comparison of its thermal conductivity in the liquid state with the other alkalis. Then, Na data will be presented in more detail. In units of cal/[cm^2·s·(K/cm)], the liquid-state values of thermal conductivity λ are for Li, 0.09; for Na, 0.18; for K, 0.10; and for Rb, 0.075. Sodium is seen to be almost twice as favorable as the other alkali liquid metals in this respect. A detailed survey of sodium and sodium–potassium alloy (NaK) has been presented by Jackson and his collaborators (1955). A treatment of the design and performance of liquid-metal (sodium and NaK) heat exchangers and steam generators has been given by Brooks and Rosenblatt (1953). As Sittig (1956) emphasizes, sodium and its alloys have many advantages as heat-transfer media. Besides their heat-transfer coefficients being among the highest known, they are very stable in that they do not normally polymerize, carbonize, or decompose. Table 1 in Sittig's book summarizes some of the significant properties of sodium and other high-temperature heat-transfer fluids. Rather than reproduce that quantitative detail here, we list below an extensive variety of practical engineering uses of Na, which are referred to by Sittig (1956, Chap. 5).

1. Heat-transfer medium in sodium-cooled valves for aircraft engines.
2. Heat-transfer media for control of casting-head temperature for die-casting machines.
3. Shale-oil retort—solved industrial heat-transfer problem.
4. High-temperature reaction kettles.
5. Control of glass mold temperatures.
6. Nuclear power plants. Advantages of liquid Na include, in addition to high heat-transfer coefficient, (a) fairly low neutron-absorption cross section, (b) high boiling point, (c) lack of attack on ordinary metals at high temperatures, and (d) extreme thermal stability.

Table 4 collects quantitative data from two different experimental sources on the thermal conductivity of Na in the liquid state as a function of temperature. A simple linear formula [compare Eq. (1) for liquid Ga] quoted in the footnote of Table 4 gives a quantitative fit of both sets of experimental data.

7. SOURCES OF DEVIATION FROM WIEDEMANN–FRANZ LAW

Although the measurement of Lorenz number by the Kohlrausch method, discussed in Sec. 3, shows for Ga and for Hg that deviations from the theoretical value of Eq. (14) are barely outside experimental error, there are certainly cases where this is not true in general (see, for instance, Tankeshwar and March, 1996). Thus it is of interest here to summarize briefly some theoretical work on the foundations of the Wiedemann–Franz law. This has a long history and for metals has been well reviewed by Chester and Thellung (1961) and by Ziman (1960). Though the discussions were oriented in the main toward solid metals, it is worth emphasizing at this point that the theoretical result for the Lorenz number L in Eq. (14) does not depend on such details as the density of electron states, the origin of the scattering, etc., but it is based on the assumption of elastic scattering. In liquid metals focussed on here, this is discussed, for instance, by Rice (1970). His conclusion (see also Egelstaff, 1992) was that only minor corrections to Eq. (14) for L were to be expected in molten metals from inelastic scattering of electrons.

Table 4. Thermal conductivity of liquid Na [cal/(cm^2) s (°C/cm)].

181.7	0.1984	0.1955
181.8	0.1993	0.1955
235.7	0.1888	0.1893
267.5	0.1847	0.1856
269.3	0.1847	0.1854
374.3	0.1728	0.1732
375.1	0.1730	0.1731
496.2	0.1601	0.1590
512.5	0.1587	0.1571

[a] Simple linear formula used is $\lambda = 0.2166 - 0.000116t$, with t in °C (see book by Sittig, 1956).

However, Tankeshwar and March (1996) have plotted the Lorenz number versus atomic number for some 30 metals, and their results are reproduced in Fig. 4. Though we have cautioned earlier about the difficulties of direct measurement of $\lambda(T)$, it seems inescapable that there are in many cases quite substantial deviations from the theoretical prediction (14), shown by the dashed line in Fig. 4.

Most recently, therefore, attention has been focussing, though again mainly with solid metals in mind, on the contribution at high temperatures from electron–electron scattering. There is an important review, but again on solid metals, by Kaveh and Wiser (1984) that can leave no doubt as to the importance of electron–electron scattering in solid metals at high temperatures. Certainly some of their ideas and theoretical framework are relevant to the metallic liquids under discussion. But more specifically addressed to the question of the constancy, or otherwise (see Fig. 4), of the Lorenz number is the work of Schulz and Allen (1995), which appeared as this article was nearing completion. This is a very detailed study of transport in metals in the presence of electron–electron scattering. The problem of electron–electron scattering is treated by techniques that enable the different scatter-

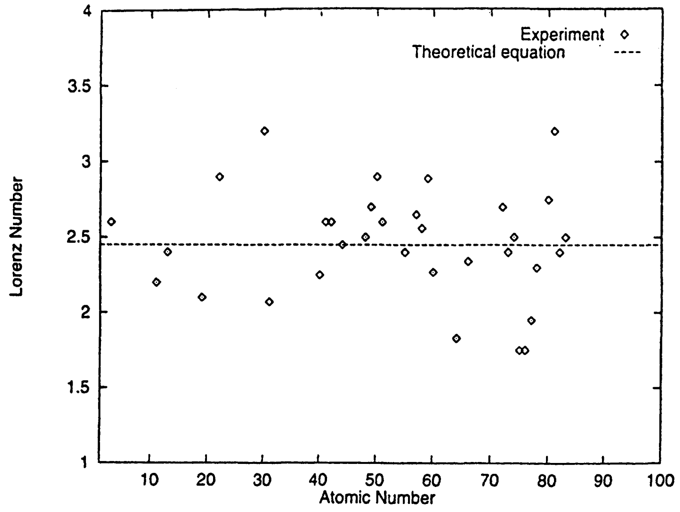

FIG. 4. Variation of experimentally determined Lorenz number (10^{-8} W K^{-2}) of metals with atomic number, after Tankeshwar and March (1996).

ing mechanisms (electron–electron, impurity, and electron–ion) to be treated on the same footing. The attack is based, as usual, on the solution of the Boltzmann transport equation (see, for example, Ziman, 1960) and use of a special set of basis functions. Results for thermal and electrical conductivity, as well as explicit results for Lorenz number, are plotted in detail by Schulz and Allen, which enables the relative importance of the different scattering mechanisms to be assessed. There is little doubt that their approach has considerable relevance for metallic liquids, but detailed applications are not available at the time of writing. However, as in the work of Kaveh and Wiser (1984), they place stress on the importance of electron–electron scattering at high temperature.

8. CONVECTION, PRANDTL NUMBER, AND INSTABILITIES

There is considerable interest at the time of writing in the continuing study of the transition to chaos. Best known is probably the Bénard instability encountered in convection. Consider a layer of fluid heated from below and held at a fixed temperature at the top. Provided the temperature is sufficiently low, heat transfer is by conduction. But when the gradient reaches a critical value, a macroscopic motion begins in the fluid. The heated parts expand and will move upward, being cooled, and then fall back again to the bottom. This motion is well regulated. Typically one observes rolls, but hexagons, seen from above, have also been noted. When the temperature is further raised, the rolls start a wavy motion along the axis—a motion that varies with time. Ultimately the orderly pattern breaks up and a chaotic motion ensues.

The basic equations governing the Bénard motion of the system are (compare Lundqvist *et al.*, 1988, p. 14)

1. the Navier–Stokes equation, in which one adds the force of gravity $\mathbf{F} = (0,0,g)$;
2. the equation of heat conduction,

$$\frac{dT}{dt} = \lambda\nabla^2 T, \tag{28}$$

and

3. the equation of continuity,

$$\frac{\partial\rho}{\partial t} + \nabla\cdot(\rho\mathbf{v}) = 0. \tag{29}$$

One must impose the boundary conditions that $T = T_0 + \Delta T$ at the bottom and $T = T_0$ at the top. The above partial differential equations governing this problem—namely convection or Bénard instability—can be transformed into a set of ordinary differential equations for the Fourier components of the various hydrodynamical quantities. E. N. Lorenz (1963) truncated these equations, taking only the leading Fourier component into account. This type of Bénard convection experiment provides examples of pattern formation in systems far from equilibrium. One of the (various) dimensionless quantities of interest in such systems is the so-called Prandtl number, $C_p\eta/M\gamma$, which is related (see Egelstaff, 1992) to the similar ratio $M\lambda/k_B\eta$. This latter number evidently connects the thermal conductivity λ with the shear viscosity η. This latter ratio has been compared and contrasted for metallic and insulating liquids by Ascough *et al.* (1988), to whose article the interested reader is referred.

9. SUMMARY

On the basis of simple assumptions of elastic scattering and degenerate conduction electrons, the electronic contribution to the thermal conductivity of a liquid metal is related to its electrical conductivity via the Lorenz number L having the value given in Eq. (14). As Fig. 4 demonstrates, while the predicted Lorenz number for degenerate electrons represents a useful average of the available data, considerable fluctuations occur about this simple prediction of the Wiedemann–Franz law. Some discussion has been given of useful techniques for measuring the thermal conductivity of liquid metals. One example, that of liquid In taken through its freezing point, has demonstrated that for this metal there are marked changes in thermal and electrical conductivities separately at the freezing point but only a relatively mild change in Lorenz number in passing through the phase transition.

INTRODUCTION

Materials may be conveniently classified as gases, liquids, and solids at a fixed set of conditions, that is, temperature, pressure, and composition. However, a given material can exist in each of these states under the appropriate conditions, barring chemical decomposition at elevated temperatures. On a microscopic scale, the state of a material is defined by the interactions among the molecules in the material and hence on their interatomic potentials. The solid phase is characterized by a high degree of order, symmetry, and structure in the system. This article does not consider the solid phase. The liquid and gas phases have much less structure, and the properties of these phases are increasingly dependent on collisions between molecules and correlated groups of molecules as the density of the fluid decreases.

Simple model intermolecular potentials have characteristic distance and energy parameters. For instance, the Lennard–Jones potential can describe molecules like noble gases, which are spherical and nonpolar; more complex molecular systems can be described by *effective* Lennard–Jones parameters. For a pure (model) Lennard–Jones fluid, the reduced temperature T_r is related to the temperature T and the energy parameter ϵ by $T_r = kT/\epsilon$, where k is Boltzmann's constant, while the reduced density ρ_r is related to the density ρ and the distance parameter σ by $\rho_r = 2\pi N_a \sigma^3 \rho/3$, where N_a is Avogadro's number. Alternatively, on a macroscopic level, the reduced temperature and density of a pure material can be related to the temperature ($T_r = T/T_c$) and density ($\rho_r = \rho/\rho_c$) at its gas–liquid critical point. The equilibrium and transport properties of all fluids exhibit sim-

ilarity when they are plotted in terms of these reduced temperatures and densities. This similarity between the properties of all fluids in terms of reduced parameters has led to the development of several very successful corresponding-states theories, which are considered in more detail in later sections.

This similarity of fluid properties, which forms the basis of the corresponding-states principle, can be used both as a predictive tool and as a consistency check for equilibrium and transport properties. For instance, data on several pure fluids can be used to predict the properties of another pure fluid or a mixture of several components. Just as corresponding-states theory can be used to relate the properties of several fluids, thermodynamic- and transport-property theory can be used to relate properties in the liquid, vapor, and supercritical phases to microscopic intermolecular potentials. Thus, even though this article focuses on the thermal conductivity (λ) of a liquid, it is necessary to consider the behavior of thermal conductivity, thermal diffusivity (a), density (ρ), and specific heat capacity at constant pressure (C_p) in the vapor and supercritical regions.

The thermal conductivity of a material has dimensions of energy per unit time, length, and temperature, and the SI units are $\mathrm{W \cdot m^{-1} \cdot K^{-1}}$. This linear transport coefficient is defined by Fourier's law for heat conduction,

$$\mathbf{J}_q = \lim_{|\nabla T| \to 0} (-\lambda \nabla T), \tag{1}$$

where $\mathbf{J}_q$ is the heat-flux vector (in power per unit area) and T is the absolute temperature. Measurement of transport properties, such as the thermal conductivity, requires a small perturbation from equilibrium conditions to approximate the limiting zero gradient in Eq. (1). Thus, thermal conductivity is defined in the limit of zero temperature gradient, viscosity (η) is defined in the limit of zero shear gradient, and mass diffusivity (D) is defined in the limit of zero chemical-potential gradient. The requirement of a small, but finite, temperature gradient introduces several complications in experimental measurements, which must be carefully considered in the liquid phase.

The density of most fluids (water near the solid line is an exception) decreases as the temperature increases when the pressure is held constant. A temperature gradient is required to determine the thermal conductivity according to Eq. (1) in any measurement device, or heat-transfer application, and so there are also density gradients introduced in the fluid. A fluid, unlike a solid, is free to flow in response to these density gradients, and free convection may result. This can lead to measurement errors and discrepancies between experimental data sets since the definition of thermal conductivity assumes that the fluid is stationary. Secondly, the molecules in the fluid, or solid, can absorb and emit thermal radiation. Since there is a temperature gradient present, energy will be transferred by radiation from high-temperature regions of the fluid and its surroundings to lower-temperature regions. Emission and absorption of radiation occur at the molecular level at discrete wavelengths according to the spectra of energy levels available in the fluid and the absolute temperature of the fluid. For heat-transfer calculations, it is convenient to integrate these discrete levels over all wavelengths to obtain an average gray-body absorption/emission coefficient for the fluid. The radiative transfer of heat from one element of fluid at T_1 to another at T_2 is given by

$$J_q = \sigma \epsilon_g (T_1^4 - T_2^4) \approx \sigma \epsilon_g T^3 (T_1 - T_2), \tag{2}$$

where σ is the Stefan–Boltzmann constant, ϵ_g is the average gray-body emissivity, and T is the average absolute temperature. Equation (2) shows that the heat transported by thermal radiation increases in proportion to the cube of the absolute temperature. Furthermore, it is proportional to the temperature gradient in the fluid and is difficult to separate from heat transfer due to thermal conduction.

In general, the heat flux is often due to a combination of several different modes of heat transfer and may include contributions from conduction, convection, radiation, boiling, condensation, etc. To deal with this complicated situation, engineers have developed the concept of a heat-transfer coefficient (U_h) that is defined implicitly by

$$J_q = U_h (T_1 - T_2) = U_h \Delta T, \tag{3}$$

where ΔT is defined according to the situation. The parameter U_h is a lumped, macroscopic quantity that is usually correlated in terms of the thermophysical properties of the materials involved. For instance, the linearization of the Stefan–Boltzmann Eq. (2) allows the radiative heat flux to be written

$$J_q = \sigma\epsilon_g T^3(T_1 - T_2) = U_h(T)\Delta T, \tag{4}$$

so $U_h = \sigma\epsilon_g T^3$ for the case of pure radiative heat transfer. In the case of heat transfer due to free convection (buoyancy driven), the heat-transfer coefficient is correlated in terms of several characteristic dimensionless parameters of the fluid. The classical correlation for heat transfer due to free convection at a vertical surface is in terms of the Nusselt number

$$\begin{aligned} N_{\mathrm{Nu}} &= \frac{U_h L}{\lambda} = c_h N_{\mathrm{Gr}}^m N_{\mathrm{Pr}}^m \\ &= c_h\left(\frac{L^3\rho^2 g_c \beta\Delta T}{\eta^2}\right)^m \left(\frac{C_p\eta}{\lambda}\right)^m, \end{aligned} \tag{5}$$

where N_{Gr} is the Grashof number, N_{Pr} is the Prandtl number, the parameters c_h and m are correlated for a given geometry, L is the characteristic length, g_c is the gravitational constant, β is the volumetric coefficient of thermal expansion, and C_p is the isobaric specific heat of the fluid. For convection, boiling, and condensation heat transfer, ΔT is the difference between the surface temperature and the bulk fluid temperature outside of the film region of the fluid where large temperature gradients exist. The heat-transfer coefficient determined from Eq. (5), $U_h = \lambda N_{\mathrm{Nu}}/L$, can then be used in Eq. (3); effects due to free convection will dominate in a situation like this over conductive and radiative contributions. Much literature is devoted to engineering heat-transfer correlations; the interested reader will find a good introduction in the book by Bird *et al.* (1960) and a general summary in the handbook by Perry *et al.* (1984).

The dimensionless parameters used in heat-transfer correlations require accurate thermophysical property data both in the development of heat-transfer correlations and in their subsequent use. Detailed finite-element or finite-difference computer simulations of complex heat-transfer situations are possible but have the same requirements for accuracy in the underlying thermophysical property data. These required data include thermal conductivity, thermal diffusivity, viscosity, density, specific heat, radiative emissivity, phase-change enthalpy, and interfacial tension. This article concentrates on the thermal conductivity but cannot be limited to thermal conductivity. The thermal conductivity is normally measured as a function of temperature, pressure, and composition, but it is most conveniently correlated in terms of temperature, density, and composition. This requires an accurate equation of state to calculate the liquid density. The thermal diffusivity a is the key property for transient heat transfer in fluids and is defined as

$$a = \frac{\lambda}{\rho C_p} = \frac{\text{(energy transport)}}{\text{(volumetric storage of energy)}}. \tag{6}$$

Thermal diffusivity has units of m²/s, as do the binary mass diffusion coefficient D_{12} and the viscous diffusivity ν. Thus, in addition to thermal conductivity, either thermal diffusivity or the fluid density and specific heat are required to describe transient conduction through fluids.

1. THEORETICAL APPROACHES

1.1 Thermal Conductivity from a Molecular Viewpoint

The physical basis for the conduction of heat energy in terms of the molecular constituents of a fluid system can be understood from a classical point of view. The particles in a fluid possess kinetic energy because of their thermal motion, internal energy related to electronic, vibrational, and rotational excitations, and potential energy associated with intermolecular interactions or external fields. These forms of energy can be interchanged through collisional processes and can be carried by the thermal motion of the molecules. When a temperature gradient is present in a fluid system, the flow of energy re-establishes the equilibrium state defined by the fundamental laws of statistical physics. This relaxation to equilibrium in response to a perturbing temperature gradient, as distinguished from processes related to macroscopic mass flow (convection) or electromagnetic radiation, is the mechanism of thermal conduction. In this article, we confine ourselves to linear phenomena in nonreactive systems, which practically involves small departures from equilibrium and small temperature gradients. The phenomenological macroscopic definition of the thermal conductivity, Fourier's law of heat conduction, was given in Eq. (1). In this section, we will relate Eq. (1) and the value of λ to microscopic processes in a fluid system.

The simplest crude model that we consider is a fluid subjected to a steady-state one-dimensional temperature gradient in the x direction, and in which the flow of energy is assumed to be due to the molecular transport of the system's internal energy per molecule, U. Thus, in Fig. 1, we assume that at $x = -l$, a local equilibrium at temperature T_1 is achieved, so that the particle carries an energy $U(T_1)$. We further assume a mean free path of l and that there is no change in the value of $U(T)$ when a particle moves through this distance. If the average speed of a particle is $\langle v \rangle$ at the origin, and $\frac{1}{6}$ of the particles at $x = -l$ move in the positive x direction and $\frac{1}{6}$ of the particles at $x = l$ move in the negative x direction, we can write the energy flux crossing the zero line as

$$J_q = \tfrac{1}{6}\langle v \rangle n[U(T_1) - U(T_2)], \tag{7}$$

where n is the number density of particles in the fluid. A Taylor expansion of the energy about $U(T_0)$ gives

$$U(T_1) = U(T_0) - l\frac{dU(T_0)}{dx}, \tag{8}$$

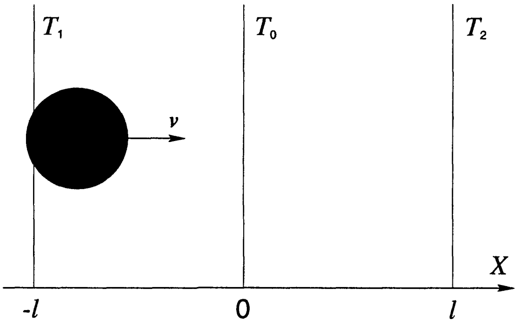

FIG. 1. Molecular transport of heat in a one-dimensional temperature gradient.

so that the energy difference in the brackets of Eq. (7) becomes $-2l dU/dx$. Without concerning ourselves, for the moment, about the additional state-variable dependence in U, we can write

$$n\frac{dU}{dx} = n\frac{dU}{dT}\frac{dT}{dx} = \rho C_v\frac{dT}{dx}, \tag{9}$$

where C_v is the molar specific heat (at constant volume) and ρ is the molar density. With this information, we can now combine Eqs. (1) and (7) to find

$$\lambda = \tfrac{1}{3}\langle v \rangle l \rho C_v. \tag{10}$$

This simple kinetic model is not unreasonable, especially in the dilute system, although we have ignored collisional transfer (in which energy is transported not through the movement of the molecules, but through their interaction) and have not dealt explicitly with the internal degrees of freedom in a molecule. Equation (10) can be evaluated in a more complete approach, and the rigorous solution for a dilute hard-sphere system gives

$$\lambda_0^{hs}(T) = \frac{25}{32}\left(\frac{kT}{\pi m}\right)^{1/2}\frac{C_v}{N_a\sigma^2}, \tag{11}$$

where σ is the hard-sphere diameter and m is the molecular mass. This expression can be considered a starting point for theoretical approaches that consider liquid-state properties from density expansions about the dilute region, that can incorporate collisional transfer and intramolecular energy processes, and that use more realistic interparticle potentials. Although Eq. (11) was derived for the dilute-gas regime, and effective hard-sphere diameters can generally be found to describe such gases, in Table 1 we show some effective liquid hard-sphere diameters derived from this formalism. As expected, effective liquid hard-sphere diameters are significantly smaller than the dilute-gas values, because we have ignored several important effects, as mentioned above.

1.2 Kinetic Theory of Thermal Conductivity

The more formal kinetic theory of thermal conductivity starts from a study of the N-particle distribution function f_N and the

Table 1. Effective hard-sphere diameters of selected liquids at the normal boiling point; from Eq. (11).

Fluid	T (K)	C_v ($\mathrm{J \cdot mol^{-1} \cdot K^{-1}}$)	λ ($\mathrm{W \cdot m^{-1} \cdot K^{-1}}$)	σ^{eff} liquid (nm)	σ^{eff} dilute (nm)
Argon	87	22.3	0.128	0.131	0.468
Water	373	67.9	0.679	0.174	0.572
R134a	247	86.5	0.104	0.294	0.858
Toluene	384	140.7	0.111	0.416	1.013
Methanol	338	72.9	0.191	0.288	0.702
Propane	231	64.0	0.129	0.275	0.850

Liouville equation, which describes its time evolution. Quantum versions of these equations, in terms of Wigner distribution functions, are also available. To solve for the thermal conductivity, equations for f_N are written in terms of coupled equations for distributions representing fewer particles. Approximations can be used to decouple these equations. The Boltzmann equation (BE) for a dilute system of structureless particles can be written in terms of the single-particle distribution $f(\mathbf{v},\mathbf{r},t)$ where $f(\mathbf{v},\mathbf{r},t) \times d^3v\, d^3r\, dt$ gives the number of particles with a velocity in the infinitesimal range about $\mathbf{v}$, at a position near $\mathbf{r}$, at a time near t. The equilibrium distribution is the Maxwell–Boltzmann expression, and collisional processes that conserve mass, momentum, and energy ensure that this equilibrium is achieved. In the presence of small linear driving forces, the single-particle distribution can be considered a perturbation of the equilibrium solution, and the BE can be solved when the interparticle potential is known. Thus, Eq. (11) can be generalized to monatomic structureless systems interacting with realistic potentials (Millat *et al.*, 1996), such as the Lennard–Jones 12-6 potential, the m-6-8 potential (Hanley and Klein, 1972), or the Aziz–Chen potential for argon (Aziz and Chen, 1977), with the classic first-order result

$$\lambda_0(T) = \frac{\lambda_0^{hs}(T)}{\Omega^{*(2,2)}(\Phi,T)}. \tag{12}$$

In this expression, $\Omega^{*(2,2)}$ is a reduced collision integral, which is a functional of the interparticle potential $\phi(r)$.

To account for the internal degrees of freedom that can affect energy flow, Eucken (1913) developed an *ad hoc* correction factor associated with this expression; Enskog, who (with Chapman) is credited with solving the dilute-gas BE, also extended the approach to dense systems of hard-sphere fluids; see Chapman and Cowling (1939) and Hirschfelder *et al.* (1954). To deal with polyatomic fluids, instead of using the Boltzmann equation, we can use a kinetic equation in which the distribution functions have additional variables, and energy exchange among internal and kinetic modes is allowed (McCourt *et al.*, 1991a; Millat *et al.*, 1996). For instance, instead of the single-particle distribution above, we can write $f(\mathbf{v},\mathbf{j},\mathbf{r},t)$ where $\mathbf{j}$ is the rotational angular momentum of a nonspherical molecule. Such kinetic equations have been developed in classical, semiclassical (by Wang Chang *et al.*, 1964), and quantum (by Waldmann, 1957 and Snider 1960) (WS) approaches, although the solutions to such equations are substantially more difficult.

To see how the approaches progress, we can write the evolution of the single-particle distribution as

$$\left[\frac{\partial}{\partial t} + \mathbf{v}\cdot\nabla\right] f = \mathfrak{S}(f,f_1), \tag{13}$$

where the left-hand side includes the streaming term, which indicates how particle flow changes f, and the right is the collision term, which indicates the effect of interactions between particles in the specified state and particles with general coordinates $\mathbf{v}_1$, $\mathbf{r}_1$, which will be integrated over. In the Boltzmann equation, we have

$$\mathfrak{S} = \int d^3v_1 \int_0^{2\pi} d\epsilon \int_0^{\infty} b\,db|\mathbf{v}_1 - \mathbf{v}| \times \left[f(\mathbf{r},\mathbf{v}',t)f(\mathbf{r},\mathbf{v}_1',t) - f(\mathbf{r},\mathbf{v},t)f(\mathbf{r},\mathbf{v}_1,t)\right], \tag{14}$$

where collisions cause particles to enter state points with the primed velocities and leave states with the unprimed velocities. In this expression, ϵ represents the angle between the velocity vectors of the incoming particles, b is the impact parameter of the collision, and the velocities are constrained to conserve momentum and kinetic energy. Note that the BE describes collisions taking place at a point, which may be an appropriate approximation for dilute systems only. In the Waldmann–Snider equation, the collision term can be written as

$$\begin{aligned}\mathfrak{S} = \mathrm{Tr}_1 \int d^3v_1 \sum_j P_j \\ \times \left[\int d^3\epsilon a(E;\boldsymbol{\epsilon},\boldsymbol{\epsilon}')|\mathbf{v}_1' - \mathbf{v}'|f'f_1'a^\dagger(E;\boldsymbol{\epsilon},\boldsymbol{\epsilon}') \right. \\ \left. - \frac{4\pi\hbar}{m}\mathrm{Im}[a(E;\boldsymbol{\epsilon},\boldsymbol{\epsilon})ff_1]\right]P_j, \qquad (15)\end{aligned}$$

where the trace gives the quantum mechanical statistical average, P_j projects onto the specified (rotational) state, and a and $a^\dagger$ are annihilation and creation operators for energy level E with specified directions ϵ for the relevant velocity vectors. With either collision term, the kinetic equation, Eq. (13), is solved using the continuity equations for mass, momentum, and energy. The thermal conductivity is found by identifying the coefficient of the temperature gradient in an expression for the heat-flux vector.

A microscopic expression for the classical heat-flux vector of Eq. (7) can be written as

$$\begin{aligned}\mathbf{J}_q = \int d^{6N}\Gamma f_N(\Gamma,t)\left[\sum_i \mathbf{v}_i\left[\frac{mv_i^2}{2} + \frac{1}{2}\sum_j \phi_{ij}\right]\right. \\ \left. - \frac{1}{2}\sum_{ij} \mathbf{r}_{ij}\mathbf{v}_i\cdot\mathbf{F}_{ij}O_{ij}\right]\delta(\mathbf{r} - \mathbf{r}_i), \qquad (16)\end{aligned}$$

where Γ represents the full $6N$-dimensional phase space, $\mathbf{v}_i$ is the peculiar velocity of particle i (the particle velocity minus the macroscopic streaming velocity), ϕ is the interparticle potential, F is the interparticle force, and O is an operator that can incorporate certain nonlocal effects. The solution of the integro-differential kinetic equation is not trivial, but formal solutions for polyatomic gases have been obtained; see the monograph by McCourt *et al.* (1991a). Instead of the collision integral $\Omega^{*(2,2)}$ described in Eq. (12), we can write the polyatomic solution in terms of related effective cross sections (which can be associated with matrix elements of the operators in the kinetic equation) as

$$\begin{aligned}\lambda_0^{\mathrm{poly}}(T) = \lambda_0^{hs}(T)\pi\sigma^2\frac{4R}{5C_v} \\ \times \frac{\mathfrak{S}(1001) - 2r\mathfrak{S}\begin{pmatrix}1010\\1001\end{pmatrix} + r^2\mathfrak{S}(1010)}{\mathfrak{S}(1010)\mathfrak{S}(1001) - \mathfrak{S}^2\begin{pmatrix}1010\\1001\end{pmatrix}}, \\ (17)\end{aligned}$$

where R is the universal gas constant, the indices on the effective cross sections $\mathfrak{S}$ refer to matrix elements associated with elastic collisions, internal energy states, and inelastic collisions, and r^2 is the ratio of the rotational heat capacity to the translational portion of the isobaric heat capacity.

The formal result of Eq. (17) serves to motivate the Eucken correction, which provides a more empirical attempt to extend the kinetic-theory results from monatomic to more complex molecular systems. Mason and Monchick (1962) made their theoretical arguments from a more classical approach (Millat *et al.*, 1996). We can write

$$\lambda = \lambda^{\mathrm{trans}} + \lambda^{\mathrm{int}} \qquad (18)$$

to separate effects due to transport of translational energy and interchange with internal (intramolecular) energy of a molecular fluid. Instead of an expression like Eq. (11), we then use

$$\lambda_0^{\mathrm{trans}} = \epsilon_{\mathrm{trans}}\frac{C_v^{\mathrm{trans}}}{C_v}\lambda_0^{\mathrm{mon}} \qquad (19)$$

and

$$\lambda_0^{\mathrm{int}} = \epsilon_{\mathrm{int}}\frac{C_v^{\mathrm{int}}}{C_v}\lambda_0^{\mathrm{mon}}, \qquad (20)$$

where Eq. (12) gives the monatomic result λ_0^{mon}, the isochoric heat capacity has been divided into its translational and internal contributions, and ϵ is a measure of the relative efficiencies of energy transport by these mechanisms. In this notation, $\epsilon_{\mathrm{trans}}$ is often approximated as 1, ϵ_{int} is $\frac{2}{5}$, $C_v^{\mathrm{trans}} = 3R/2$, and $C_v^{\mathrm{int}} = C_v - C_v^{\mathrm{trans}}$. These approximations correspond to fast interchange between translational and rotational energy states and correspond to the original Eucken correction in the dilute limit:

$$\lambda_0 = \left(\frac{9\gamma}{10} - \frac{1}{2}\right)\lambda_0^{\text{mon}}, \tag{21}$$

where γ is the ratio of heat capacities, C_p/C_v. We can develop improved approximations from the Wang Chang–Uhlenbeck deBoer equation or from the solution to the Waldmann–Snider equation, Eq. (17), where the cross terms in the translational–rotational energy exchange are related to a diffusional process. An improved estimate for a modified Eucken correction gives $\epsilon_{\text{int}} \approx 0.528$ (Reid *et al.*, 1987), and the full Mason–Monchick calculation gives values of ϵ_{trans} and ϵ_{int} in terms of the self-diffusion coefficient, the rotational contribution to the heat capacity, the viscosity, and a rotational collision number (or a related relaxation time). The value of λ_{int} is often assumed to be independent of density, and thus the dilute-gas value discussed here is combined with a density-dependent value for λ^{trans} to calculate the thermal conductivity at arbitrary state points, including the liquid phase. Although this assumption cannot be strictly true, it is often sufficient to obtain an estimate or correlation for $\lambda_0^{\text{int}}(T)$ and use this value at all densities.

Before we conclude this long section on kinetic theory, we briefly discuss another microscopic approach to the calculation of thermal conductivity. A simple expression for conservation of energy, the heat-conduction equation, can be written, using Eq. (1), as

$$\rho C_v \frac{\partial \tilde{E}}{\partial t} = \lambda \nabla^2 \tilde{E}, \tag{22}$$

where we are examining the time rate of change of the local excess energy $\tilde{E}$ (its local value relative to a macroscopic average) due to heat flow. Fluctuation theory tells us how to evaluate deviations from an ensemble average (McQuarrie, 1976), and we can obtain the Green–Kubo result that

$$\lambda = \frac{1}{Vk_{\text{B}}T^2}\int_0^\infty \langle \mathbf{J}_q(t)\cdot\mathbf{J}_q(0)\rangle, \tag{23}$$

where an expression for the heat-flux vector has been given in Eq. (16). This time–correlation-function formalism is especially useful in determining the thermal conductivity from equilibrium computer simulations of fluid systems.

1.3 Enskog Theory and Its Modifications

In order to extend the Boltzmann equation to higher densities, we must consider at least two modifications of Eqs. (13) and (14). First, because collisional processes have a finite spatial extent, energy can cross a boundary line, such as the zero line in Fig. 1, without any particles actually crossing this boundary. This collisional transfer process can be described, in part, by a nonlocality expansion of the operator O_{ij} of Eq. (16) or by using an analogous treatment in a kinetic equation. Second, the frequency of collisions, which is implicitly incorporated into the BE from a simple statistical argument, must be modified. This is because, in a dense system, two particles whose trajectories at time t_0 ordinarily result in a collision at a time t may be shielded by the presence of a third particle, which is not considered in the dilute-system formulation of the BE. Thus, multiparticle correlation must be considered in a dense system. Enskog provided a solution to such a problem in the special case of a hard-sphere system.

The collision term of Eq. (14) becomes

$$\begin{aligned}\mathfrak{S} = \int d^3v_1 \int_0^{2\pi} d\epsilon \int_0^\infty b\,db|\mathbf{v}_1 - \mathbf{v}| \\ \times [y(\mathbf{r} + \tfrac{1}{2}\sigma\hat{\mathbf{k}})f(\mathbf{r},\mathbf{v}',t)f(\mathbf{r} + \sigma\hat{\mathbf{k}}, \mathbf{v}_1', t) \\ - y(\mathbf{r} - \tfrac{1}{2}\sigma\hat{\mathbf{k}})f(\mathbf{r},\mathbf{v},t)f(\mathbf{r} - \sigma\hat{\mathbf{k}}, \mathbf{v}_1, t)],\end{aligned} \tag{24}$$

where $y(\mathbf{r})$ is related to the pair distribution function and $\hat{\mathbf{k}}$ is the unit vector connecting the centers of the two colliding particles. The kinetic equation can then be solved with the result

$$\begin{aligned}\lambda(T,\rho) = \lambda_0(T)B(T)\rho \\ \times \left[\frac{1}{y(T,\rho)} + 1.20 + 0.755y(T,\rho)\right],\end{aligned} \tag{25}$$

where B is the second virial coefficient ($2\pi\sigma^3/3$ for hard spheres), ρ is the fluid density, λ_0 is the dilute-gas solution of Eq. (11), and y in this Enskog theory can be equated to the residual compressibility factor, $y_{\mathrm{ET}} = P/\rho RT - 1$. This hard-sphere Enskog solution can be used directly for real fluids or for more realistic potentials by using the appropriate values for B and y. However, a modification of the Enskog result (see Hirschfelder *et al.*, 1954), also proposed by Enskog, provides a better description of dense-fluid thermal conductivity. In this modification, the MET, the pressure in the expression for y is replaced by a "thermal" pressure $T(\partial P/\partial T)|_\rho$ so that the factor becomes $y_{\mathrm{MET}} = T(\partial P/\partial T)|_\rho/\rho RT - 1$. To ensure that the expression in Eq. (25) reduces to the correct value in the dilute limit, the second virial coefficient is also replaced by $B + T\,dB/dT$. For polyatomic molecules, this approach is often associated with the translational contribution to the thermal conductivity defined in Eq. (18), and the internal contribution is treated with a density-independent Eucken factor. This approach generally gives reasonable agreement with experimental data for dense systems. In Fig. 2, we illustrate the Enskog-theory results in comparison to a correlation for the thermal conductivity of argon along an isotherm.

1.4 Corresponding-States Approaches

The thermal conductivity of a pure fluid can be generally written as

$$\lambda(\rho,T) = \lambda_0^{\mathrm{trans}}(T) + \lambda_0^{\mathrm{int}}(T) + \lambda_{\mathrm{ex}}^{\mathrm{trans}}(\rho,T) + \lambda_{\mathrm{ex}}^{\mathrm{int}}(\rho,T) + \Delta\lambda_c(\rho,T), \qquad (26)$$

where the division into translational internal contributions, discussed in Eq. (18), is incorporated into both the dilute term and the excess term λ_{ex}, and the critical enhancement $\Delta\lambda_c$ is introduced. This last contribution arises from cooperative effects associated with fluctuations near the critical point of the fluid and is discussed in Sec. 1.6. The contributions of these terms are illustrated schematically in Fig. 3. In some studies, the excess thermal conductivity is further divided; for example, a density series can be used to define a first density correction, analogous to the second virial coefficient in thermodynamic studies. The independent variables Eq. (26), the temperature and density, are the fundamental determinants of the thermal conductivity in the sense that thermal motions and collisional processes play the key roles; for a mixture, the composition variable(s) can be included. Although the single temperature variable uniquely defines the fluid state and the thermal conductivity of a pure liquid in equilibrium with its vapor (saturated liquid), it is the density variation along the saturation boundary that is most important in determining thermal conductivity.

In practice, the internal contribution to the thermal conductivity is often considered to depend only on the temperature (and thus it is always equal to its dilute-gas value), so that $\lambda_{\mathrm{ex}}^{\mathrm{int}}$ vanishes; also, the translational portion of the excess term is often considered to be independent of temperature, and the critical enhancement is significant only near the

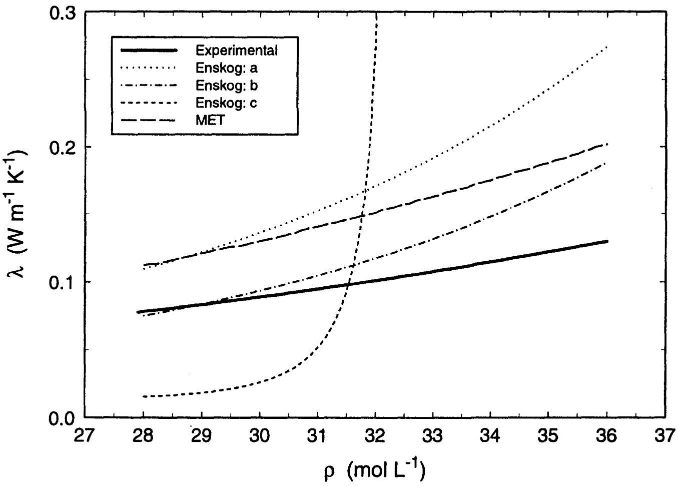

FIG. 2. Thermal conductivity of compressed liquid argon along isotherm at 125 K. Solid line is experimental correlation. Models use σ = 0.357 nm. Dotted line (a) is Enskog hard-sphere theory, dot-dashed line (b) is Enskog theory with experimental value for λ_0, short-dashed line (c) is Enskog theory with experimentally derived values of λ_0 and $y(T,\rho)$, and long-dashed line is modified Enskog theory (MET).

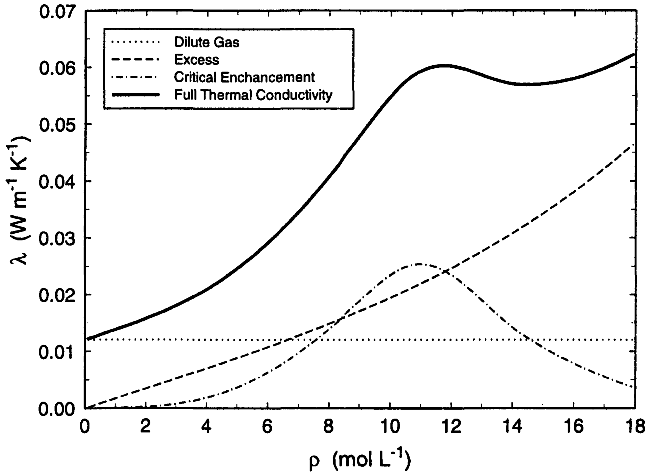

FIG. 3. Contribution of dilute gas, excess, and critical enhancement to the thermal conductivity of supercritical nitrogen at 128 K.

critical point. Although these assertions cannot be strictly true, this approximation simplifies Eq. (26) to

$$\lambda(\rho,T) \approx \lambda_0^{\text{trans}}(T) + \lambda_0^{\text{int}}(T) + \lambda_{\text{ex}}^{\text{trans}}(\rho). \tag{27}$$

The topology and amplitudes for the thermal conductivity surfaces of a wide assortment of liquids are similar. This observation has inspired the development of scaling-factor arguments that lead to corresponding-states approaches to the calculation of liquid thermal conductivity. From a molecular point of view, we can show that if the interparticle potentials of two fluids are conformal, that is, equivalent when values for an energy parameter and length parameter are properly scaled, at least the translational contributions to the thermal conductivity must also scale. This approach leads to the relationship

$$\lambda(\rho,T) = \Lambda\lambda^*_{\text{ref}}(\rho^*,T^*), \tag{28}$$

which can be applied to any or all terms of Eqs. (26) or (27). The factor Λ can be taken as $k^{1/2}\epsilon^{1/2}/m^{1/2}\sigma^2$ from kinetic-theory arguments [Eq. (11) or (23), for example], where k is the Boltzmann constant, ϵ and σ are energy and length scales (both of which can be obtained from an interparticle potential), and m is the molecular mass. Alternatively, we can include the thermodynamic $C_v(\rho,T)$ in Λ, use the viscosity (which, from kinetic theory, is directly related to the translational portion of the thermal conductivity in the dilute-gas limit), develop the length and energy scales from critical constants or thermodynamic corresponding-states approaches, or construct empirical approximations for Λ. Models in which Λ is constant can be developed, or Λ can be made a function of composition, temperature, and/or density. The relations between ρ and ρ^* and between T and T^* can again be constant (or composition-dependent) length and energy scaling factors, such as $\rho^* = \rho\rho_c/\rho_c^{\text{ref}}$ and $T^* = T_c^{\text{ref}}/TT_c$ where the subscript c indicates a critical or pseudocritical value and "ref" indicates a reference fluid, or can be density- and/or temperature-dependent transformations defined from the thermodynamic surface or from an empirical examination of thermal conductivity data. In this manner, we can relate the thermal conductivity of any liquid system (pure fluid or mixture) to that of a reference thermal-conductivity surface. The reference surface can be established from correlation of experimental data, or it can be developed from theoretical solutions of a model system.

With these corresponding-states arguments, we have formally created a mathematical mapping between the thermal-conductivity surfaces of all fluid systems. In fact, the mapping becomes simpler when the system of interest and the reference system are similar: that is, where both fluids are noble gases, nonpolar fluids, aqueous systems, etc. Because the temperature dependence of the thermal conductivity is small at high densities or effectively confined to the dilute-gas region, it is often explicitly removed from consideration to reduce the dimensionality of the problem. Even for the reference fluid, then, we can write $\lambda(\rho,T) = \Lambda^*\lambda(\rho')$. Any residual temperature dependence can be included in Λ^* and/or in the transformation between ρ and ρ' to obtain conformality of the isotherms to an arbitrary accuracy. Figure 4 illustrates this corresponding-states behavior in nearly 4200 experimental points for five compositions in the binary methane–ethane system over the temperature range from 140 to 330 K (Friend and Roder, 1987). In this illustration, all temperature dependence was incorporated in the dilute-gas term (so the residual temperature dependence is indicated in the figure), Λ^* has been set equal to 1, and the reduced density was empirically determined to be the system density divided by a simple composition-dependent reducing factor. Similarly, thermal conductivity data for a variety of liquid systems, pure fluids and mixtures, can be made to lie on a single curve in a graph of reduced thermal conductivity $\lambda^* = \lambda/\Lambda^*$ versus reduced density. There are several algorithms for achieving this corresponding-states relationship, and systematic methods for describing various classes of systems have been devised; the single curve obtained in this method can then be regressed from data or described from a theoretical description of a model system.

To make this discussion of corresponding-states calculations of thermal conductivity more explicit, we summarize an approach widely used for hydrocarbon systems, refrigeration fluids, etc. According to Eq. (26), we treat each contribution to the thermal conductivity as a separate problem. We assume that the thermodynamic surface of the fluid is known from experimental data or from an equilibrium corresponding-states algorithm. A standard thermodynamic corresponding-states model (Leach *et al.*, 1968) constructs a mapping such that the reduced residual Helmholtz energy, $(A - A^{\text{ideal gas}})/RT$, and residual compressibility factor x of the fluid of interest are (approximately) equal to that of the reference fluid when the state points are related by $\rho^* = \rho_x h_x$ and $T^* = T_x/f_x$. In this thermodynamic formalism, the equivalent substance reducing parameters, h_x and f_x, are defined by this relationship and can be related to the critical parameters or implicitly defined as temperature- and density-dependent functions depending on the details of the model. In this approach, the dilute-gas contributions are assumed to obey a corresponding-states relation in the sense that a single potential model, with parameters estimated from data or from a scheme involving the critical parameters and the acentric factor, is used to solve for the translational portion of the collision integral, Eqs. (11) and (12). An Eucken correction is used for the internal contributions, such that the value of C_v^{int} of Eq. (20) is approximated as $C_p^{\text{ideal}} - 5R/2$ and ϵ_{int} becomes a temperature-dependent function, $\epsilon_1 + \epsilon_2 T_c/T$, which can be fitted to dilute-gas data or assumed to obey a corresponding-states principle. This term is considered independent of the density. The factor Λ of Eq. (28) for the translational contribution can be taken as a temperature- and density-dependent function,

$$\Lambda = (M_{\text{ref}}/M)^{1/2} f_x^{1/2} h_x^{-2/3}, \tag{29}$$

which can be further modified to take into account shape dependences by including a multiplier based on the acentric factors of the fluids. This approach can be used for mixtures (Ely and Hanley, 1983), in which case the effective molar mass M can be a function of the mole fractions, molar masses, and equivalent substance reducing ratios of each of the components, and the scheme can be extended to include a corresponding-states approach for the critical-region enhancement.

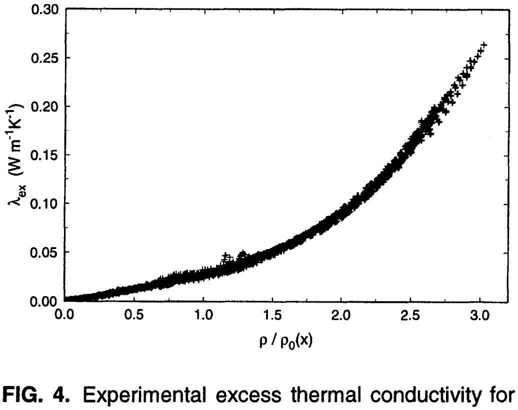

FIG. 4. Experimental excess thermal conductivity for methane–ethane mixtures as a function of reduced density.

1.5 Hard-Sphere Liquids

In Eq. (25), we have given a kinetic-theory solution for the thermal conductivity of a hard-sphere fluid, and a model for rough spheres can be shown to give a result directly proportional to this expression. This can be combined with the dilute hard-sphere gas solution, Eq. (11), with $C_v = 3R/2$. In an expression for $\lambda^{hs}/\lambda_0^{hs}$, the molecular size parameter appears explicitly only as a factor of σ^2. This motivates a factor of $\rho^{2/3}$ in the definition of Λ in Eq. (28). A corresponding-states expression based on these observations, which has been successfully applied to a variety of liquids, is

$$\lambda(\rho,T) = \hat{R}_\lambda \rho^{2/3} T^{1/2} M^{-1/2} \lambda^*(\rho^*). \tag{30}$$

In this expression, λ^* is treated as a universal curve for liquids that can be obtained from the hard-sphere result or regressed from available data. The reduced density is defined by $\rho^* = \rho/\rho_0(T)$, where ρ_0 is related to an effective hard-sphere diameter and has a weak temperature dependence. The reducing parameter $\rho_0(T)$ shows a systematic behavior for various families of fluids and can be regressed from available viscosity and self-diffusion data as well as thermal conductivity data in a consistent approach to all three transport coefficients (Assael *et al.*, 1992a). The factor $\hat{R}_\lambda$ includes contributions from the hard-sphere result as well as an empirical factor R_λ, which represents a deviation from hard-sphere behavior, or roughness factor, which can account for internal contributions to the thermal conductivity. The multiplier R_λ also shows a systematic behavior within a family of molecules and generally has values somewhat greater than 1 (Assael *et al.*, 1992a); it can also be adjusted to have temperature dependence to describe the thermal conductivity of polar liquids (Assael *et al.*, 1994, 1995; Bleazard and Teja, 1996).

1.6 Critical-Region Behavior

The critical point of a fluid system has been discussed in the article CRITICAL PHENOMENA. It has been identified as the point at which the order parameter takes on a nonzero value (from above) and a symmetrical phase is broken into a phase with lower symmetry—e.g., liquid–vapor phase separation. Several thermodynamic properties exhibit divergences at this point, and dynamical properties also show enhancements. Microscopic fluctuations are known to play a dominant role in this region, and critical slowing down becomes important for transport processes. The renormalization-group approach for thermodynamics can be extended to a dynamical renormalization group, and model systems or mode-coupling approaches can be used to understand the behavior of the thermal conductivity in this region. Observationally, the thermal conductivity exhibits an enhancement in the critical region, which is most easily observed for pure fluids along supercritical isotherms. The thermal conductivity reaches a maximum on this path, which is centered near the critical density and is nearly symmetrical around this density. The maximum approaches infinity as the temperature approaches the critical temperature, and an enhancement, although small, may be seen for some systems at temperatures up to about twice the critical temperature. In Fig. 5, we show the critical-region behavior of the thermal conductivity of carbon dioxide. In the compressed-liquid state, isotherms terminate on the saturation boundary, and so the critical density is not accessible. Nonetheless, along liquid isotherms at higher temperatures, the critical enhancement is also present and becomes dominant as the critical temperature is approached. Although it is difficult to isolate this critical-enhancement contribution to the liquid thermal conductivity at lower temperatures in order to ascertain its extent, this phenomenon must be considered in any general description of liquid-phase thermal conductivity.

A phenomenological explanation of the critical enhancement of the thermal conductivity can be developed from the relation between the thermal diffusivity and thermal conductivity given in Eq. (6): $a = \lambda/\rho C_p$. We combine this with the simple Stokes–Einstein expression for the diffusion of particles in a fluid medium, $D = kT/6\pi\eta R$, where D is the diffusion coefficient, η is the fluid viscosity, and R is the radius of the spherical particle. Because the density fluctuations have a correlation length of ξ, we consider the thermal diffusivity as a diffusive process of these

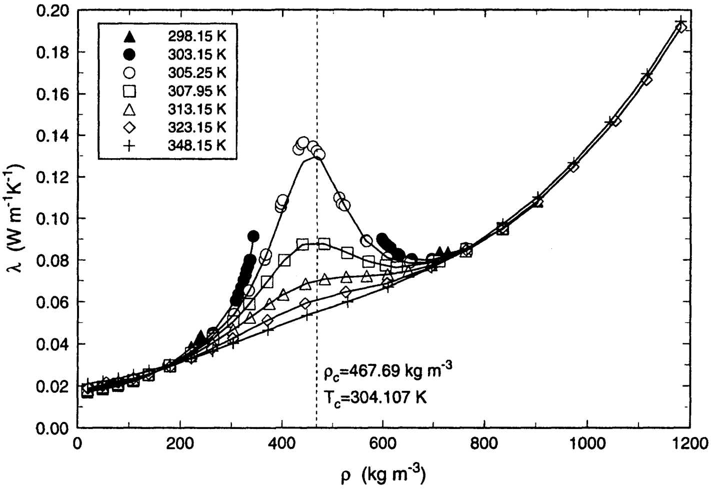

FIG. 5. Thermal conductivity of carbon dioxide in the critical region as a function of density along several isotherms. The experimental data are those of Michels *et al.* (1962). The solid curves are calculated from the correlation of Vesovic *et al.* (1990).

fluctuations that equates *a* to *D* with the result

$$\lambda = \rho k T C_p / 6\pi\eta\xi. \qquad (31)$$

The divergence of the thermal conductivity comes about, in this formalism, from the strong critical divergence of the isobaric heat capacity (with critical exponent near 1.2 along the critical isochore). Both the correlation length and the viscosity in Eq. (31) also diverge, but these critical exponents are significantly smaller. Although the asymptotic behavior of the thermal conductivity described by Eq. (31) may be confined to a very small region around the critical point and is thus difficult to achieve, the general character of the thermal conductivity surface is consistent with this asymptotic behavior.

In order to describe the effect of critical-region fluctuations throughout the range of their influence, the first four terms in Eq. (26) are often combined to form a background term $\lambda_b(\rho,T)$, so that the critical enhancement is empirically defined by $\Delta\lambda_c(\rho,T) = \lambda(\rho,T) - \lambda_b(\rho,T)$. This definition is ambiguous, and it is based on the concept that the background should be well behaved throughout a complete range of temperature and density. This implies that a description of a background thermal-conductivity surface developed from data well outside the critical region can be extrapolated into the critical region with reliable results. The critical enhancement can then be correlated either empirically or with a theoretically based crossover formalism, which attempts to bridge the range of independent variables between the asymptotic critical region of Eq. (31) to the region in which the fluctuation-induced behavior becomes negligible. The enhancement can be described empirically by a Gaussian function (Roder, 1982) such as

$$\Delta\lambda_c(T,\rho) = F(T)\exp[-A(\rho - \rho_c)^2], \qquad (32)$$

where the temperature-dependent amplitude *F* is strongly peaked or infinite at the critical temperature and *A* is an empirical width parameter. Alternatively, we can use the asymptotic form of Eq. (31) and write

$$\Delta\lambda_c = R\,\frac{\rho k T C_p}{6\pi\eta\xi}\,\tilde{\Omega}(T,\rho), \qquad (33)$$

where *R* is a universal amplitude with a value of approximately 1.02. The damping function $\tilde{\Omega}$ has been considered empirically (Sengers, 1985), often with an overall multiplicative thermodynamic factor of $(C_p - C_v)/C_p$. More recently, approximate solutions to the mode-coupling equations have become available (Olchowy and Sengers, 1988; Perkins *et al.*, 1991b). Thus $\tilde{\Omega}$ can be expressed in terms of the thermodynamic quantities, background values for the viscosity and thermal conductivity, and a single system-dependent wave-number cutoff. This cutoff represents a maximum wave number (or minimum wavelength) above which the critical fluctuations do not contribute to $\Delta\lambda_c$. The correlation length in Eq. (33) can also be estimated from thermodynamic quantities and is related to the fluid's isothermal compressibility.

This discussion of the critical-region enhancement is appropriate for pure fluids, but the problem for mixtures is more complicated. In fact, however, these approaches have been used with some success for both pure-fluid and mixture corresponding-states calculations of the thermal conductivity (Huber *et al.,* 1992). The nature of the order parameter for mixture critical phenomena depends on whether the fluid is near a vapor-liquid critical line or a liquid–liquid critical line, and the behavior of the thermal conductivity must be considered accordingly. This problem has received considerable recent attention, and much progress has been made in this area (Luettmer-Strathmann and Sengers, 1996). We conclude this section by noting that for liquid systems of both pure fluids and mixtures, explicit incorporation of the critical enhancement contribution can be ignored as long as the state point is sufficiently far from the critical region. In this case, contributions from this process may be implicitly included in an empirical description of the thermal-conductivity surface, but extreme care must be taken not to extrapolate such a surface into the critical region.

1.7 Computer Simulation of Thermal Conductivity

Advances in computer technology have made it possible to examine complex thermal conduction problems and evaluate liquid thermal conductivity by simulating the microscopic behavior of the fluid constituents. This enables us to examine in detail the assumptions underlying the theoretical and correlational approaches to thermal conductivity, including the kinetic processes, the interaction between internal and external degrees of freedom, and the sensitivity to details of the intermolecular interactions. In principle, computer simulations can complement or even supplant experimental determinations of heat-transfer processes, especially for extreme regions of temperature, pressure, or chemical reactivity where physical experiments become difficult but simulation experiments remain tractable. The equations of motion in a computer simulation are often based on Newtonian dynamics, although additional constraints can be included to ensure that the ensemble temperature remains constant, intramolecular bonds are maintained, etc. To augment the number of particles in a simulation, which cannot approach the Avogadro number, which quantifies the number of molecules in a real macroscopic system, periodic boundary conditions are often used. Additionally, to make the problem tractable, short-range potentials or cutoff length scales are used to reduce the number of force pairs that must be considered. Simulation algorithms for the calculation of thermal conductivity can be divided into two major classifications, equilibrium molecular dynamics (MD) and nonequilibrium molecular dynamics (NEMD), which we discuss briefly, in turn.

It may be intuitively difficult to see how an equilibrium simulation can determine parameters for dynamical processes such as the transport of heat energy in a temperature gradient; however, the Green–Kubo expression for the thermal conductivity, Eq. (23), expresses just this relationship. The thermal conductivity tells us the rate at which fluctuations in temperature relax to equilibrium in the context of an autocorrelation function for the heat-flux vector. In a classic simulation for thermal conductivity by Alder *et al.* (1970), an integral of the heat-flux vector was monitored for a system of 108 particles interacting through a hard-sphere repulsion. Thus the thermal conductivity was evaluated from

$$\lambda = \frac{1}{2Vk_{\mathrm{B}}T^2 s} \times \left\langle \left[\sum_{i=1}^{N} x_i(t+s)E_i(t+s) - x_i(t)E_i(t) \right]^2 \right\rangle, \tag{34}$$

where N is the number of particles and s is the time step in the simulation. Thus each particle's position x and total energy E_i (or rather each component of the position and energy) are monitored at every time, and the simple differencing and time averaging of Eq. (34) is performed to obtain the thermal conductivity. This simulation gave excellent agreement with the Enskog result of Eq. (25), and even allowed examination of the separate contributions from the kinetic, potential, and cross terms in the theoretical approach. However, questions remained concerning the long-time behavior of the autocorrelation function within a finite ensemble of particles.

More recent equilibrium MD simulations have focussed on more realistic potentials, such as the Lennard–Jones 6–12 potential, and have included simulations of liquid mixtures (Hoheisel and Vogelsang, 1988). The heat-flux vector itself, defined microscopically by an expression similar to Eq. (16), can be used directly as an alternative to Eq. (34), and various simulation ensembles have been used. Even without explicitly accounting for internal degrees of freedom or the angular dependence in the intermolecular potential, reasonable results for liquid thermal conductivity can be obtained from a simulation based on Eq. (23) using effective parameters for the particle interactions. For noble-gas fluids, *ab initio* potential surfaces based on spectroscopic data can be used within the Green–Kubo formalism in MD simulations. For supercritical liquidlike states of neon, for example, the differences between MD results and experimental thermal conductivities are less than 10% (Eggenberger *et al.*, 1992). For polyatomic fluids, potentials based on a rigid-rotor model for nitrogen, for example, have been used for dilute-gas calculations based on a Monte Carlo evaluation of the collision integrals such as in Eq. (12) (Heck and Dickinson, 1994). These nonisotropic potential surfaces for nonspherical systems are intrinsically more difficult to incorporate in MD simulations.

Nonequilibrium molecular dynamics (NEMD) is a computer-simulation technique that more closely parallels the experimental determination of transport coefficients based on their definition, such as Eq. (1). The computer "particles" respond with a steady-state nonequilibrium flux to a driving thermodynamic force, the temperature gradient. An alternative NEMD algorithm uses a fictitious heat-field vector $\mathbf{F}_q$, which corresponds to $-\nabla \ln T$ in the sense that it drives a heat-flux vector. In this case, $\mathbf{F}_q$ contributes to the time rate of change of each particle's momentum, but the thermodynamic temperature is constrained to be constant in the system. A heat-flux vector is given by

$$\mathbf{J}_q = \frac{1}{V}\sum_{i=1}^{N} \mathbf{v}_i e_i - \tfrac{1}{2}\sum_{i,j\neq i} \mathbf{r}_{ij}\mathbf{F}_{ij}\cdot\mathbf{v}_i \tag{35}$$

for an N-particle system, with e_i representing the total energy of particle i; this is a straightforward implementation of Eq. (16). The thermal-conductivity coefficient is a time average defined by

$$\lambda = \lim_{F_q \Rightarrow 0} \langle \mathbf{J}_q \cdot \mathbf{F}_q / T F_q^2 \rangle \tag{36}$$

in analogy to Eq. (1). This NEMD method has been very successful for atomic fluids and has been extended to polyatomic fluids by including rotational degrees of freedom and torque terms in the equations of motion (Hanley and Evans, 1996); potentials based on site–site interactions for a molecular fluid such as benzene have also been used (Ravi *et al.*, 1992). Resultant thermal conductivities are found that agree very well with experimental results, and the mechanisms contributing to the heat-transfer process can be studied in controlled microscopic detail (Millat *et al.*, 1996).

2. EXPERIMENTAL TECHNIQUES

Experimental techniques for the measurement of thermal conductivity can be classified according to their mode of operation. Thus, thermal-conductivity measurement techniques are generally either steady state or transient. Temperatures and heat fluxes can be either measured directly or inferred from optical measurements of refractive-index gradients or fluctuations. Some techniques measure thermal conductivity directly, while others measure thermal diffusivity, from which thermal conductivity can be calculated using Eq. (6), assuming that both density and isobaric heat capacity are known with sufficient accuracy. Some transient techniques are capable of measuring both thermal conductivity and thermal diffusivity (Perkins *et al.*, 1991a), thus providing a consistency check for both quantities if the isobaric specific heat and density are well known. Alternatively, measurements of both thermal diffusivity and thermal conductivity can be used with density data to obtain estimates of the isobaric specific heat of a fluid (Matos Lopes *et al.*, 1995). Acoustic techniques are available to measure thermal conductivity and thermal diffusivity, but are presently restricted to the gas phase and will not be discussed here.

Generally some temperature gradient is imposed on the fluid and the heat flux is measured. Thus in the general sense, it is a heat-transfer coefficient, or apparent thermal conductivity, that is measured. The principal experimental problem during thermal-conductivity determinations is to minimize heat transfer from mechanisms other than pure conduction, such as thermal radiation and convection. These parasitic heat-transfer mechanisms are always present to some extent and can become significant for certain fluids under certain temperature and density conditions in even the most carefully designed experiment. Nieto de Castro *et al.* (1986) showed a plot of the accepted value of the thermal conductivity of saturated liquid toluene as a function of the year measured. In 1920 the accepted value was about 150 $\mathrm{mW \cdot m^{-1} \cdot K^{-1}}$ at 300 K with an uncertainty of about 5%. The accepted value decreased steadily so that it was about 8–10% lower in 1968, as understanding of the effects of convection and thermal radiation on the measurements increased. The encouraging news is that the accepted value for this substance has remained relatively constant since 1968, and toluene is recommended as a standard reference fluid by the International Union of Pure and Applied Chemistry (IUPAC) (Nieto de Castro *et al.*, 1986).

Instruments to measure thermal conductivity can be classified as relative or absolute instruments. Relative instruments require a well-characterized calibrating fluid such as toluene or water. Many instruments are operated in a relative fashion because of inadequacies in their working models. It may not be adequate to calibrate with a single fluid, since measurements of another fluid may involve extrapolation of the calibration. Calibration with two fluids is preferable, especially if the two fluids have properties that lie on either side of the fluid of interest. Measurements are then based on interpolation, rather than extrapolation, between the two reference fluids. Absolute measurements require knowledge of properties such as cell geometry, temperature, pressure, voltage, and resistance. Standard reference thermal-conductivity surfaces are established from measurements with absolute instruments and are useful to check the proper operation of new and modified absolute instruments.

2.1 Heat Transfer Including Radiation and Convection

Three differential equations are required to describe combined heat and momentum transfer and must be solved simultaneously in the general case with no heat generation in the fluid. These are the continuity equation, the equation of motion, and the conservation of energy equation. The continuity equation is

$$\frac{\partial}{\partial t}\rho = -\nabla \cdot (\rho \mathbf{v}), \tag{37}$$

where ρ is the fluid density and $\mathbf{v}$ is the fluid velocity. The momentum equation or equation of motion is

$$\frac{\partial}{\partial t}\rho \mathbf{v} = -\nabla \cdot [\rho \mathbf{v}\mathbf{v}] - \nabla \cdot \boldsymbol{\tau} - \rho g_c \beta (T - \bar{T}), \tag{38}$$

where $\boldsymbol{\tau}$ is the shear stress tensor ($\boldsymbol{\tau} = -\eta \nabla \mathbf{v}$), g is the gravitational constant, and $\bar{T}$ is the average fluid temperature. Finally, the conservation of energy is given by

$$\begin{aligned}\frac{\partial}{\partial t}\rho C_p T = {} & -\nabla \cdot (\rho C_p T \mathbf{v}) - \nabla \cdot (\mathbf{J}_q \\ & - \mathbf{J}_r) - (\boldsymbol{\tau}:\nabla \mathbf{v}) + \left(\frac{\partial \ln V}{\partial \ln T}\right)_p \frac{Dp}{Dt} \\ & + \rho T \frac{DC_p}{Dt},\end{aligned} \tag{39}$$

where $\mathbf{J}_r$ is the radiant flux and the hydrodynamic derivative $D/Dt = \partial/\partial t + \mathbf{v} \cdot \nabla$. Steady state is reached when the temperature at any given position does not vary with time ($\partial T/\partial t = 0$), and transient terms, which are dependent on time t, are eliminated.

Equations (37)–(39) are simplified significantly when the thermophysical properties are constant, an accurate assumption for small temperature gradients, and when there is no pressure gradient or viscous dissipation. These equations become

$$\nabla \cdot \mathbf{v} = 0, \tag{40}$$

$$\rho \frac{\partial \mathbf{v}}{\partial t} = -\rho \nabla \cdot \mathbf{v}\mathbf{v} + \eta \nabla^2 \mathbf{v} - \rho \mathbf{g} \beta (T - \bar{T}), \quad (41)$$

and

$$\rho C_p \frac{\partial T}{\partial t} = -\rho C_p \nabla \cdot T\mathbf{v} + \lambda \nabla^2 T - \nabla \cdot \mathbf{J}_r. \quad (42)$$

Equations (40)–(42) describe processes in which heat transfer from conduction, free convection, and thermal radiation are all present in the limit of a small temperature difference. Equation (42) indicates that the energy storage is the sum of convection plus conduction plus radiation heat transfer. Equations (42) and (6) show that, in the absence of convection ($\mathbf{v} = 0$), the thermal diffusivity of the fluid can be found from a transient experiment. All three of these equations must be considered for any real thermal conduction experiment. Experiments to measure the thermal conductivity of a fluid strive to minimize the contributions from free convection and thermal radiation, while using the most simple geometries possible.

2.2 Steady-State Techniques

Steady-state techniques confine the fluid of interest between two surfaces at different temperatures in a simple, easily modeled geometry. A constant, steady-state heat flux is emitted by the hot surface, and the temperature difference between the two surfaces is recorded. The ideal model assumes that all of the heat emitted by the hot surface is absorbed by the cold surface and that heat transfer is purely by thermal conduction. This is an approximation, so that parasitic heat losses from edges and ends must be minimized and carefully accounted for, often with the aid of measurements in vacuum. Convection in the fluid can be detected and characterized by a study of the measured apparent thermal conductivity as a function of the applied power or the measured temperature difference. Pure thermal conduction has no power dependence on the assumption that the limit of the gradient of temperature approaching zero is effectively realized (although the thermal properties are themselves temperature dependent), so that the apparent thermal conductivity is nearly constant when there is no convection. Absorption and re-emission of thermal radiation by the fluid can be detected and characterized by varying the gap between the two surfaces of the measurement cell. If the contribution of thermal radiation is significant, the apparent thermal conductivity will be a function of the gap spacing, since the optical path length between the two measurement surfaces is changing. Generally, small gaps are preferred to minimize both convection and radiation corrections and errors. Additionally, the surfaces of the measurement cell should have low infrared emissivities to minimize thermal radiation contributions for both transparent and absorbing fluids.

The experimental thermal conductivity of the fluid is given by

$$\lambda = C_{\text{cell}} J_{\text{app}} / \Delta T, \quad (43)$$

where C_{cell} is the cell constant of the steady-state instrument and is defined by the geometry of the instrument. For any geometry, it is necessary to know the cell constant of the instrument to obtain the thermal conductivity of the fluid from the measured applied power J_{app} and temperature rise ΔT. The cell constant of absolute instruments can be obtained from a careful characterization of the cell dimensions and the coefficients of thermal expansion of the materials of construction. Alternatively, the cell surfaces can be used as capacitor plates, so that a vacuum measurement of the ac electrical properties of the cell provides a direct measurement of the cell constant. In the case of relative instruments, the cell constant is obtained through the use of Eq. (43) for one or more reference fluids of known thermal conductivity. The common geometries for steady-state thermal conductivity instruments are parallel plates, concentric cylinders, and heated wire in a cylinder.

The parallel-plate instrument is perhaps the most simple geometry, but is not easily used at very high pressures. Convection in parallel-plate instruments is suppressed by placing the hot plate above the cold plate; the temperature gradient cannot drive free convection. This technique has been used to get within several millikelvins of the gas–liquid critical point. The concentric-cylinder instrument has significant advantages for use at very high pressures. This geometry is normally operated so that the cylindrical axis is vertical. Thus, even though convection can be suppressed through the use of narrow gaps between the hot and cold cylinders, the concentric-cylinder technique is not the method of choice in the critical region where convection is a severe problem. Finally, the hot-wire technique is easy to set up and use from low to extremely high pressures. The hot-wire technique is generally more prone to fluid convection errors than even the concentric-cylinder technique, since the gap between the wire and the outer cylinder is larger than the gap in most concentric-cylinder instruments. Parasitic heat loses are generally minimized through the use of guard heaters at the ends of the plates or cylinders. Consult Le Niendre *et al.* (1991) for a more detailed discussion of steady-state measurement techniques.

2.3 Transient Techniques
